Speech map in the human ventral sensory-motor cortex
David Conant¹,², Kristofer E Bouchard¹,² and Edward F Chang¹,²

The study of spatial maps of the ventral sensory-motor cortex (vSMC) dates back to the earliest cortical stimulation studies. This review surveys a number of recent and historical reports of the features and function of spatial maps within vSMC towards the human behavior of speaking. Representations of the vocal tract, like other body parts, are arranged in a somatotopic fashion within ventral SMC. This region has unique features and connectivity that may give insight into its specialized function in speech production. New methods allow us to probe further into the functional role of this organization by studying the spatial dynamics of vSMC during natural speaking in humans.

Introduction
Speaking is a unique and defining human behavior. It is carried out by precise, controlled movements of different parts of the vocal tract, known as articulators, which are closely coordinated with the larynx and respiration. Speech articulation is often described as the most complex motor behavior because over 100 muscles are involved, and the movements occur on an extremely rapid time scale. Despite its complexity, nearly all of us learn to master this skill to speak fluently and effortlessly [1].

A key brain area in the neural control of articulation is the ventral portion of the sensory-motor cortex (vSMC). Injuries to this area produce motor deficits in articulation, called dysarthria [2]. In comparison to the dorsal sensory-motor cortical regions involved in arm reaching and hand function, the neurobiology of vSMC is relatively understudied. The vSMC features some important anatomic and functional differences from dorsal sensory-motor cortex, while sharing others. For example, in contrast to the dorsal areas, vSMC projects via the corticobulbar tract to the oro-facial motor nuclei, and ultimately to the articulatory muscles. vSMC has connections with higher-order cortical areas such as the anterior cingulate and supplementary motor area, basal ganglia, and cerebellum.

In classic studies, the vSMC has been described by its somatotopic organization of face and oro-pharynx representations. These areas are involved in controlling such non-speech movements as facial expressions, tongue movements, and swallowing. However, over the past decade we have begun to learn more about how this same cortical area mediates a totally different functional purpose in the production of vocal speech.

The goal of this review is to address the functional organization of the vSMC in the context of speaking, broadly focused on three central topics: firstly somatotopy of speech articulator representations, secondly potential neuroanatomical specializations for speech in humans, and thirdly organization of distributed spatial patterns of cortical activity during speech.

The somatotopy of speech articulators in vSMC
Electrical stimulation studies provided the earliest description of the human vSMC somatopy from Foerster and Penfield [3]. The popular conception of vSMC organization features a highly stereotyped, discretely ordered progression of representations for the lips, jaw, tongue, and pharynx/larynx, respectively, along the dorsal-to-ventral orientation of the central sulcus (Figure 1a) [4**,5–8]. However, the full details of their qualitative descriptions actually portray a more complex picture of organization. Cortical regions representing separate, but neighboring, body parts occupied overlapping regions of cortex such that a given point on vSMC may fall within the region for several, neighboring body parts. Generally, there was a strong bias for motor responses on the precentral gyrus and somatosensory responses on the postcentral, but this boundary is not absolute: motor and sensory responses have been described on both gyri [4**,9].

Some examples of motor responses evoked by cortical stimulation are contralateral pulling of the mouth, twitching of the lips, simple opening or closing of the mouth, or swallowing. Sensory responses were usually reported as tingling in a given body part, sometimes with extreme precision, for example, the tip of the contralateral upper tooth. Responses rarely if ever corresponded to proprioceptive sensation or the perception of movement [4**].

Utilizing the increased spatial resolution of intracortical microstimulation (ICMS) in non-human primates
With the advent of functional imaging such as PET and fMRI it became possible to noninvasively study humans during vocalization, with enough spatial resolution to investigate somatotopic maps. These studies have generally recapitulated the stimulation findings about the cortical representation of the lips, jaw and tongue [17–19,20*,21].

While there is agreement about the general somatopic layout of the lips, jaw and tongue in vSMC, there have been inconsistencies in the localization of the larynx representation. Some studies have placed it at the most dorsal position of vSMC, which is similar to the conclusions of many studies in both humans and primates [21–23,24*]. Others have noted a laryngeal motor area just dorsal of the lip representation [20*,21,25**]. This more dorsal location has not been described in NHPs, but it is located near sites that vocalization has been elicited using stimulation in humans [2,4**]. While the existence of somatotopy in vSMC is fairly clear, its consequences for control of speech production are not clear.

Recently, electrocorticography (ECoG) was used to investigate the functional organization of ventral sensorimotor cortex during a task in which patients produced a large number of consonant-vowel syllables [26**]. ECoG in humans can be carried out in specific clinical conditions and involves the surgical implantation of an array of electrodes directly on the cortical surface, thereby providing high spatial and temporal resolution. Unlike the unnatural and simple movements of single articulators evoked by electrical stimulation, the production of meaningful speech sounds requires the precisely coordinated control of multiple articulators. The authors leveraged the variability in articulatory patterns associated with this large corpus of speech sounds to quantitatively assign a dominant articulator (lips, jaw, tongue, or larynx) representation to the cortical activity recorded at each electrode. Because of the superior temporal resolution of ECoG, cortical activity could be parsed out at the level of phonemes.

In this fashion, the cortical organization of all articulators could be derived without the need to isolate the movement of articulators using non-speech tasks or a limited set of carefully chosen speech sounds with constrained production. Although articulator representations were partially overlapping in both space and time, a dorsal-to-ventral organization of articulator representations was found (Figure 1b). This organization featured two separate representations of the larynx, with one site located ventral to the tongue, and the other dorsal to the lips. The dorsal representation is approximately the same as those seen in fMRI [20*,25**], but the ventral representation is similar to sites for throat seen in human stimulation studies [2,4**]. The presence of this more dorsal site which was found over the precentral gyrus has not been described in NHP, and raises an interesting question.

(NHPs), which applies a small amount of current at varying depths in the cortex, the localization of individual muscles rather than body parts was possible. This technique confirmed the somatotopic organization, but revealed that individual muscles did not appear to have a somatotopic organization, and there were multiple loci that evoked movement from the same muscle [10*,11–13]. More recent ICMS studies in NHPs have shown that stimulating motor regions for a relatively long time scale (500 ms) results in complex movements of muscle groups [14–16] (e.g., rhythmic jaw movements), as opposed to the simple twitches resulting from shorter stimulation. Nonetheless, it is important to note that linguistically meaningful sounds such as simple syllables or words have never evoked during stimulation [2,4**].
about differences between humans and NHPs that may have a role in the production of speech. Evidence using transcranial magnetic stimulation in humans suggests a potential differentiation between localized representations of laryngeal muscles, with the cricothyroid muscle dorsally and the vocalis ventrally. Evoked movements of the vocalis in the ventral region have been confirmed using direct cortical stimulation as well [27,28].

Specializations within human vSMC for speech
NHPs have largely homologous orofacial anatomical structures and do vocalize, but do not have the capacity to produce the same repertoire of speech sounds as humans. The functional and anatomical differences between humans and NHPs with respect to speech may inform what features of oro-facial sensorimotor cortex are integral to speech production. One such difference has been evoked vocalization observed in human cortical stimulation studies. This was typically described as a prolonged phonation, sounding like ‘ahhh…’, which continues throughout the duration of the stimulation [2]. Within vSMC, these sites are clustered along the central sulcus just dorsal to the representation of the lips on the precentral gyrus [2,4**]. In NHP studies, a region in the ventral-most premotor cortex has been identified that, when stimulated, produces vocal fold movement. However, vocalization has never been produced from cortical stimulation of this or any other sensorimotor area in NHP [29–31].

Anatomically, two descending pathways exist in primates: a direct, bi-lateral projection between motor cortex and the oro-facial motor nuclei in the pontine and medullar level of the brain stem, and another indirect projection to the oro-facial motor nuclei via interneurons within the reticular formation. This indirect pathway interfaces with other descending cortical areas involved in vocal production at the reticular formation, such as the anterior cingulate cortex [10*,32,33*]. Although the direct path is found in all primates, humans have an additional direct connection from larynx motor cortex to the nucleus ambiguus, which innervates the laryngeal muscles [33*,34,35]. Given the short synaptic distance between vSMC and the muscles of the speech articulators, activity in vSMC is likely closely tied to the generation of movement of the speech articulators. Furthermore, the additional descending pathway from ventral laryngeal motor cortex found only in humans may be a neuroanatomical specialization for speech.

In humans, patients with lesions of unilateral oro-facial sensory-motor cortex suffer temporary dysarthria, or ‘thickness of speech’, but this improves with time until there is no noticeable deficit [2]. This is often also associated with deficits in nonspeech function as well, such as contralateral weakness of facial or tongue protrusion. However, bilateral loss of vSMC results in complete loss of voluntary control of the speech articulators [33*,36–38]. Together, lesion studies in humans suggest that vSMC is necessary for speech, and that there is some degree of redundant bilateral control [16,39].

Lesion studies from NHPs suggest a specific role for ventral motor cortex in producing learned vocalizations. In NHPs, oro-facial motor cortex can be removed without affecting unlearned species-specific vocalizations [40,41]. However, if the animal is trained to do a task that involves precise volitional oro-facial control (e.g., produce constant force with the tongue), deactivation of sensorimotor cortex results in pronounced deficits [41,42]. This implies that oro-facial motor cortex is specifically recruited in the control of learned, volitional oro-facial tasks, and not more innate vocal behaviors [33*,41]. This discrimination between innate and learned vocal behaviors is thought to arise at the level of the direct versus indirect pathway; the direct is necessary for volitional articulator control while the indirect is necessary for innate orofacial behaviors [25**,33*].

A great deal of the evidence above points towards a special role of the larynx representation within vSMC for speech. More so than any other part of vSMC, the larynx seems to carry inconsistencies between humans and NHP that are relevant to speech. It has been proposed that the functional and anatomical differences in laryngeal motor representation may underlie some differences in capacity for speaking [25**,26**,33*]. It appears to represent an important exception to the general principles of somatotopic organization of the sensorimotor cortex and warrants further investigation.

What is the functional organization of speech sounds?
The somatotopic maps up to this point describe the representation of individual articulators on the cortical surface. However, the generation of speech sounds is not accomplished through the simple movement of a single articulator, but rather the precise coordination of multiple articulators. Therefore, in order to understand the functional organization of speech in vSMC it is necessary to move away from static descriptions of somatotopy and instead analyze the population-derived spatial patterns of cortical activity during unconstrained production of a variety of speech sounds. Bouchard et al. used principal component analysis to transform the population neural activity into a ‘cortical state-space’ that best describes the cortical patterns associated with the produced syllables. Capitalizing upon the high temporal resolution of ECoG, it was possible to temporally disambiguate the cortical activity associated with consonants and vowels (Figure 2).

An examination of the organization of both consonants and vowels in this cortical state-space revealed that
different phonemes were clustered according to the major oral articulators engaged during production (i.e., the dorsal tongue, coronal tongue, and lips). Furthermore, a detailed analysis of phoneme representations revealed a rich, hierarchical organization of ‘phonetic features’, which also emphasized the major oral articulators, but additionally demonstrated that the place of constriction within a given articulator was the secondary organizing principle, followed by the degree of constriction. Therefore, the spatial patterns of cortical activity across multiple speech articulators were used to understand the organization of phoneme representations across the vSMC network. This organization likely reflects the coordinative patterns across articulatory motions during speech. The somatotopic and phonemic feature maps during speech production are both important principles of vSMC mesoscale spatial organization. Deriving the mathematical mapping from somatotopic organization to phonemic feature organization in this way is critical to understanding the role of somatotopy in speech production.

**Conclusions**

Previous research has described the basic organization of maps within human sensorimotor cortex, but we are only beginning to understand the functional significance of vSMC somatotopy in speech. Many of the same questions that were investigated decades ago are still relevant to the study of speech production today. What is the relevance of somatotopy to models of speech motor control? Where does the precise coordination of articulators originate? How does vSMC functionally relate to other speech areas? To what degree is the vSMC activity for a phoneme categorical and to what degree does it depend on surrounding phonemes? New tools that afford increased spatial and temporal precision to record brain activity, combined with more detailed monitoring of speech articulators, will allow us to more fully address these questions in the near future.
