Systems evolving according to effective non-Hermitian Hamiltonians are considered. To each eigenvalue of the effective Hamiltonian is associated two eigenstates which evolve backward and forward in time, respectively. Adiabatic measurements on such systems are analyzed. The outcome of the adiabatic measurement of an observable is the weak value associated with the two-state vector. The possibility of performing such measurements in a laboratory is discussed.

PACS numbers: 03.65.Bz

Any interaction between two systems can be regarded, in a very wide sense, as a “measurement” since the state of one of the systems, the measuring device, is affected by the state of the other one, the measured system. In general, however, this interaction is not very “clean,” that is, the information about the properties of the measured system cannot be read easily from the final state of the measuring device. Only some very particular classes of interactions are clean enough and are called measurements in the usual, more restricted, sense.

The best known type of quantum measurement is the von Neumann ideal measurement wherein the system is coupled impulsively to the measuring device. The Hamiltonian describing such a measurement is

\[ H = H_0 + g(t) PA + H_{MD}, \]

where \( H_0 \) is the free Hamiltonian of the system, \( H_{MD} \) is the free Hamiltonian of the measuring device, \( P \) is the momentum conjugate to the position variable \( Q \) of the pointer of the measuring device, and \( A \) is the observable to be measured. The coupling parameter \( g(t) \) is normalized to \( \int g(t) \, dt = 1 \) and is taken to be nonvanishing during a very small interval \( \Delta t \). Thus, the interaction term dominates the rest of the Hamiltonian during \( \Delta t \), and the time evolution \( e^{-iPA} \) leads to a correlated state: eigenstates of \( A \) with eigenvalues \( a_n \) are correlated to measuring device states in which the pointer is shifted by these values \( a_n \) (we use units such that \( \hbar = 1 \)). Thus in an ideal measurement the final state of the measuring device is very simply related to the state of the measured system. The properties of ideal measurements are as follows: (a) The outcome of the measurement can only be one of the eigenvalues \( a_i \). (b) A particular outcome \( a_i \) appears at random, with probability that depends only on the initial state of the measured system and is independent of the details of the measurement. (c) The measurement leads to the (true or effective, depending on one’s preferred interpretation) collapse of the wave function of the measured system on the eigenstate \( |a_i\rangle \).

Subsequent ideal measurements of the same observable invariably yield the same eigenvalue \( a_i \).

The opposite limit of extremely weak and long interaction is also clean enough to be called a measurement [1,2] (whether it should be called a measurement of an observable is discussed in [3,4]). In such an adiabatic (or protective) measurement, the coupling is very small: \( g(t) = 1/T \) for most of the interaction time \( T \) and \( g(t) \) goes to zero gradually before and after the period \( T \). In order that the measurement be as clean as possible, we also impose that the initial state of the measuring device is such that the momentum \( P \) is bounded, that the momentum \( P \) is a constant of motion of the whole
Hamiltonian equation (1) (but we shall only consider the simpler case where $H_{MD}$ vanishes), and that the free Hamiltonian $H_0$ has nondegenerate eigenvalues $E_i$. For $g(t)$ smooth enough we then obtain an adiabatic process in which the system cannot make a transition from one energy eigenstate to another, and, in the limit $T \to \infty$, the interaction Hamiltonian changes the energy eigenstate by an infinitesimal amount. If the initial state of the system is an eigenstate $|E_i\rangle$ of $H_0$, then, for any given value of $P$, the energy of the eigenstate shifts by an infinitesimal amount given by the first order perturbation theory: $\delta E = \langle E_i|H_{int}|E_i\rangle = \langle E_i|A|E_i\rangle P/T$. The corresponding time evolution $e^{-iP(E_i|A|E_i)P/T}$ shifts the pointer by the expectation value of $A$ in the state $|E_i\rangle$. The main properties of adiabatic measurements are as follows: (a) The outcome of the measurement can only be the expectation value $\langle A \rangle_i \equiv \langle E_i|A|E_i\rangle$. (b) A particular outcome $\langle A \rangle_j$ appears at random, with a probability which depends only on the initial state of the measured system and is independent of the details of the measurement. (c) The measurement leads to the collapse of the wave function of the measured system on the energy eigenstate $|E_i\rangle$ corresponding to the observed expectation value $\langle A \rangle_i$. Subsequent adiabatic measurements of the same observable $A$ invariably yield the expectation value in the same eigenstate $|E_i\rangle$. (d) Simultaneous measurements of different observables yield the expectation value in the same energy eigenstate $|E_i\rangle$.

The aim of the present Letter is to consider measurements on systems which evolve according to an effective non-Hermitian Hamiltonian. While ideal (impulsive) measurements on such systems lead to no surprise (since in an impulsive measurement the unperturbed Hamiltonian of the measured system plays no role), adiabatic measurements yield as outcomes some new type of values associated with the measured observable, namely, the “weak values” [6]. Weak values were originally introduced in the context of the two-state formalism [6–9] wherein a preselected and postselected system is described at time $t$ by two states, the usual one $|\Psi_1\rangle$ evolving towards the future from the preselection measurement, and a second state $|\Psi_2\rangle$ evolving towards the past from the postselection measurement. If at time $t$ a sufficiently weak measurement is carried out on such a system, the state of the measuring device after the postselection is shifted to $|\Psi_{MD}(Q)\rangle \to |\Psi_{MD}(Q - A_w)\rangle$, where $A_w$ is the weak value of the observable $A$,

$$A_w = \frac{\langle \Psi_2|A|\Psi_1\rangle}{\langle \Psi_2|\Psi_1\rangle}.$$  

(2)

Note that weak values can take values which lie outside the range of eigenvalues of $A$ and are in general complex. Under appropriate conditions, their real and imaginary parts affect the position and momentum of the pointer, respectively. Weak values are associated with two states which in the present context are the left and right eigenstates of the effective Hamiltonian (see below) [10]. The main properties of adiabatic measurements carried out on a system evolving according to an effective non-Hermitian Hamiltonian are as follows: (a) The only possible outcomes of the measurement are the weak values $A^\mu_w$ corresponding to one of the pairs of states $\langle \psi_i || \phi_i \rangle$ associated with the non-Hermitian Hamiltonian. (b) A particular outcome $A^\mu_w$ appears at random, with a probability which depends only on the initial state of the measured system and is independent of the details of the measurement. (c) The measurement leads to an effective collapse to the two-state vector $\langle \psi_i || \phi_i \rangle$ corresponding to the observed weak value $A^\mu_w$. Subsequent adiabatic measurements of the same observable $A$ invariably yield the same weak value. (d) Simultaneous measurements of different observables yield the weak values corresponding to the same two-state vector $\langle \psi_i || \phi_i \rangle$.

Although the Hamiltonian of a quantum system is always a Hermitian operator, under suitable conditions a subsystem may evolve according to an effective non-Hermitian Hamiltonian. A well known case is the description of metastable states [11]. If the system is initially in the metastable state $\psi(0)$, after a time $t$ it will be in the state $\psi(t) = e^{-iH_{eff} t} \psi(0) + \text{decay products}$ where $H_{eff}$ is the effective non-Hermitian Hamiltonian. A celebrated example where this description has proved extremely useful is the kaon system. Another case in which a system evolves according to an effective non-Hermitian Hamiltonian is when it is coupled to a suitably preselected and postselected system [10]. As an example, consider a spin-1/2 particle coupled to a preselected and postselected system $S$ of large spin $N$ through the Hamiltonian

$$H_0 = \lambda S \cdot \sigma.$$  

(3)

The large spin is preselected at $t_1$ to be in the state $|S_x = N\rangle$ and postselected to be at $t_2$ in the state $|S_y = N\rangle$ (when dealing with spin systems we use units of $\hbar/2$). The coupling constant $\lambda$ is chosen in such a way that the interaction with our spin-1/2 particle cannot change significantly the two-state vector of the system $S$. Indeed, the system with the spin $S$ can be considered as $N$ spin-1/2 particles all preselected in $|1\rangle_x$ state and postselected in $|1\rangle_y$ state. Since the strength of the coupling to each spin-1/2 particle is $\lambda \ll 1$, during the time of the measurement their states cannot change significantly. (However, $AN$ must be large so that the effective Hamiltonian is significant.) Thus, the forward evolving state $|S_x = N\rangle$ and the backward evolving state $|S_y = N\rangle$ do not change significantly during the measuring process. Hence, effectively, the spin-1/2 particle is coupled to the weak value of $S$.

$$S_w = \frac{\langle S_y = N | S_x = N, S_z = N \rangle | S_x = N \rangle}{\langle S_y = N | S_x = N \rangle} = (N, N, iN),$$  

(4)
and the effective non-Hermitian Hamiltonian is given by
\[ H_{\text{eff}} = \lambda N (\sigma_x + \sigma_y + i \sigma_z). \] (5)

The non-Hermiticity of $H_{\text{eff}}$ is due to the complexity of $S_w$. A detailed discussion of this example is given below.

Note that the effective non-Hermitian Hamiltonians only arise due to a partial postselection. In the spin example it only applies if the large spin is found in the state ($S_y = N$). In the case of metastable states it only applies to the metastable states so long as they have not decayed.

We now analyze the general properties of a non-Hermitian Hamiltonian $H_{\text{eff}}$ which has nondegenerate eigenvalues $\omega_i$. In general the eigenvalues are complex. Denote the eigenkets and the eigenbras of $H_{\text{eff}}$ by $|\phi_i\rangle$ and $\langle \psi_i|$.\n
\[ H_{\text{eff}} |\phi_i\rangle = \omega_i |\phi_i\rangle, \quad \langle \psi_i| H_{\text{eff}} = \omega_i \langle \psi_i|. \] (6)

Contrary to the case where $H_{\text{eff}}$ is Hermitian, the $|\phi_i\rangle$ are not orthogonal to each other, nor are the $\langle \psi_i|$ , and furthermore $|\psi_i\rangle \neq |\phi_i\rangle$. However, the $|\phi_i\rangle$ and $\langle \psi_i|$ each form a complete set, and they obey the mutual orthogonality condition
\[ \langle \psi_i| \phi_j \rangle = \langle \psi_i| \phi_i \rangle \delta_{ij}, \] (7)

which follows from subtracting the two identities $\langle \psi_i| H_{\text{eff}} |\phi_j\rangle = \omega_j \langle \psi_i| \phi_j \rangle$, $\langle \psi_i| H_{\text{eff}} |\phi_j\rangle = \omega_j \langle \psi_i| \phi_j \rangle$ for $i \neq j$. Equation (7) enables us to rewrite $H_{\text{eff}}$ as
\[ H_{\text{eff}} = \sum_i \omega_i \langle \psi_i| \phi_i \rangle \langle \psi_i| \phi_i \rangle, \] (8)

which generalizes the diagonalization of Hermitian operators. The eigenkets of $H_{\text{eff}}$ are the natural basis in which to decompose a forward evolving state $|\Phi\rangle$. Indeed, using the decomposition of unity $I = \sum_j |\phi_j\rangle \langle \phi_j| \phi_j \rangle$ one obtains
\[ |\Phi\rangle = \sum_i \langle \psi_i| \phi_i \rangle |\phi_i\rangle = \sum_i \alpha_i |\phi_i\rangle. \] (9)

(On the other hand, a backward evolving state should be decomposed into the eigenbras of $H_{\text{eff}}$ as $|\Psi\rangle = \sum_j \beta_j \langle \psi_j| |\psi_j\rangle$.) The formal solution of Schrödinger’s equation with the effective Hamiltonian $H_{\text{eff}}$ is
\[ |\Phi(t)\rangle = e^{-iH_{\text{eff}}t} |\Phi\rangle = \sum_i \alpha_i e^{-i\omega_i t} |\phi_i\rangle. \] (10)

Note that the norm $N$ of $|\Phi(t)\rangle$ is not equal to 1 but is time dependent. Formally, there are two causes for not conserving the norm in time evolution due to the effective Hamiltonian. The first is that the eigenvalues $\omega_i$ may be complex. The second is that the eigenkets are not necessarily orthogonal. This nonconservation of probability by non-Hermitian Hamiltonians has a natural interpretation when one recalls that we are describing partially postselected systems. In the case of metastable states $N(t)$ is the probability for the states not to have decayed. In the spin example $N(t)$ describes corrections to the probability of finding the state ($S_y = N$).

Let us illustrate this general formalism by considering the kaon system. The two eigenkets of the effective Hamiltonian are traditionally denoted $|K_s\rangle$ and $|K_L\rangle$. Similarly, one can define the eigenbras of the effective kaon Hamiltonian $\langle K_s|\langle K_L|$. The particular features of the non-Hermitian Hamiltonian are controlled by the $CP$ violation parameter $\epsilon \approx 10^{-3}$. The nonorthogonality of the eigenkets is $\langle K_s|K_L\rangle = O(\epsilon)$ and the nonequality of the right and left eigenstates is $\langle K_s|K_L\rangle = 1 - O(\epsilon^2)$. In view of the smallness of $\epsilon$ the adiabatic measurements which we propose below may be difficult to implement in the kaon system. However, other metastable systems may display much stronger nonorthogonality and be more amenable to experiment.

In the spin example, the effective Hamiltonian equation (5) has two eigenvalues $+\lambda N$ and $-\lambda N$ with eigenkets (eigenbras) $|\downarrow\rangle$ ($\langle \downarrow|$) and $|\uparrow\rangle$ ($\langle \uparrow|$), respectively. Thus, $H_{\text{eff}}$ can be rewritten as
\[ H_{\text{eff}} = \lambda N \frac{|\downarrow\rangle \langle \downarrow|}{\langle \downarrow| \downarrow\rangle} - \lambda N \frac{|\uparrow\rangle \langle \uparrow|}{\langle \uparrow| \uparrow\rangle}. \] (11)

In this example the eigenkets and eigenbras associated with the same eigenvalue are very different. Thus, weak values associated with these two states can have surprising behaviors. For example, $\langle \downarrow| \sigma_z \rangle / \langle \downarrow| \downarrow\rangle = 1$, which is pure imaginary and $\langle \downarrow| \sigma_z \rangle / \langle \downarrow| \downarrow\rangle = -\sqrt{2}$, which lies outside the range of eigenvalues of $\sigma \cdot n$.

Now we can discuss adiabatic measurements performed on a system evolving according to $H_{\text{eff}}$. The Hamiltonian describing such a measurement is given by Eq. (1) with $H_0$ replaced by $H_{\text{eff}}$. The coupling parameter $g(t)$ equals $1/T$ for most of the interaction time $T$ and goes to zero gradually before and after the period $T$. In order that the measurement be as clean as possible we also impose that $H_{\text{eff}}$ has nondegenerate eigenvalues, that the initial state of the measuring device is such that the momentum $P$ is bounded, and that the momentum $P$ is a constant of motion of the whole Hamiltonian equation (1). For $g(t)$ smooth enough, and in the limit $T \to \infty$, we obtain once more an adiabatic process such that if the system is initially in an eigenket $|\phi_i\rangle$, it will still be in the same eigenket after the measurement. Furthermore, in this limit, the interaction Hamiltonian changes the eigenket during the interaction by an infinitesimal amount.

If we take the initial state of the system to be an eigenket $|\phi_i\rangle$, then for any given value of $P$, the eigenvalue of the eigenstate shifts by an infinitesimal amount which can...
be obtained using first order perturbation theory as follows. The perturbed eigenstates are solutions of
\[
(H_{\text{eff}} + \frac{P}{T} A) \left( |\phi_i\rangle + \sum_{j \neq i} c_{ij} |\phi_j\rangle \right) = (\omega_i + \delta \omega_i) \left( |\phi_i\rangle + \sum_{j \neq i} c_{ij} |\phi_j\rangle \right).
\]
Taking the scalar product with \( |\psi_i\rangle \), to first order in \( P/T \) one obtains
\[
\delta \omega_i = \frac{P}{T} \left( \frac{\langle \psi_i | A | \phi_i \rangle}{\langle \psi_i | \phi_i \rangle} \right) = \frac{P}{T} A_w^i.
\]
If the initial state of the measuring device is a Gaussian \( e^{-Q^2/\Delta^2} \), then after the measurement the state of the measuring device is \( \Psi_{\text{MD}}(Q - A_w^i) = Ce^{-(Q - \text{Re} \Delta_x)^2/\Delta^2} e^{-iQ \text{Im} A_w^i/\Delta} \). Thus reading the position (momentum) of the measuring device yields the real (imaginary) part of \( A_w^i \).

It is instructive to consider the case when the initial state is not an eigenket of \( H_{\text{eff}} \). The initial state should then be decomposed into a superposition of eigenkets \( |\Phi\rangle = \sum \alpha_i |\phi_i\rangle \), and its time evolution, up to normalization, will be given by
\[
|\Phi\rangle_{\text{MD}}(Q) \rightarrow \sum \alpha_i e^{-i\omega \tau} |\phi_i\rangle_{\text{MD}}(Q - A_w^i).
\]
During the measurement process, which includes further interactions, the states of the measuring device corresponding to different values of \( A_w^i \) become macroscopically distinguishable. Then, effectively, a collapse takes place to the reading of one of the weak values \( A_w^i \) with the relative probabilities given by \( \alpha_i^2 e^{-2 \text{Im} (\alpha_i)^2 \tau} \). We call the collapse effective because it only occurs under the condition that a partial postselection is realized. A subsequent adiabatic measurement of another observable \( B \) will yield the weak value corresponding to the same two-state \( \langle \psi_i | \phi_i \rangle \). Alternatively, one can carry out the measurements of \( A \) and \( B \) simultaneously. This can always be done by increasing the duration \( T \) of the measurement so that the interaction \( (P_1 A + P_2 B) / T \) remains a small perturbation. Thus, given a sufficiently long time \( T \), one can obtain reliable measurements of any set of observables by making measuring devices interact adiabatically with a single quantum system. However, it should be noted that in any realistic implementation we will need ensembles of systems and measuring devices since both in the case of metastable states and in the spin example the probability of a successful partial postselection (which gives rise to the effective non-Hermitian Hamiltonian) is very small. Indeed, the adiabatic measurement will only be successful if the metastable states do not decay during the measurement, or if the spin \( S \) is found in the state \( |S_y = N\rangle \). Nevertheless, there is a nonzero probability that the first run with a single system and a single set of measuring devices will yield the desired outcomes.

Our general discussion was carried out for a system evolving according to an arbitrary effective non-Hermitian Hamiltonian. The spin example presented above is amenable to exact treatment, and one can investigate in this case in what limit the effective non-Hermitian Hamiltonian describes adequately the evolution of the spin-1/2 particle. We recall that the effective Hamiltonian equation (5) has two eigenkets \( |1_x\rangle \) and \( |1_y\rangle \). That \( |1_x\rangle \) should be an eigenket can easily be seen by noting that the initial state \( |S_y = N\rangle \) is an eigenstate of the free Hamiltonian \( H_0 = \lambda S \cdot \sigma \). That \( |1_y\rangle \) is an eigenket is a nontrivial prediction which can be checked by calculating the probability for the small spin, initially in the state \( |1_y\rangle \), to be in the state \( |1_y\rangle \) at an intermediate time. One finds that this probability is proportional to \( 1/N^2 \), thereby confirming that it is indeed an eigenket in the limit of large \( N \).

If the initial state of the small spin is \( |1_y\rangle \), and an adiabatic measurement of \( \sigma_x = \sigma_x \cdot \hat{\xi} \) is carried out, the eigenket \( |1_x\rangle \) should be unaffected by the measurement, and the measuring device should register the weak value \( \langle \sigma_x \rangle_w = \langle 1_y | \sigma_x | 1_y \rangle / \langle 1_y | 1_y \rangle \). In order to verify this we considered the particular case when \( \hat{\xi} = \hat{\xi} \), whereupon the analysis simplifies considerably since only the states with \( J_z = S_z + \sigma_z = N + 1, N - 1, N - 3 \) come up in the calculation. Thus, we took the Hamiltonian to be \( H = \lambda S \cdot \sigma + (P/T) \sigma_z \) during the interval \( t_1 < t < t_2 = t_1 + T \), with the initial state \( |S_y = N\rangle \) and the final state of the large spin postselected to be \( |S_y = N\rangle \). Taking the measuring device to be in the momentum eigenstate \( P \), one finds that after the postselection, at \( t = t_2 \), the state of the small spin plus measuring device is \( |1_y\rangle e^{i\theta} + \text{error terms} \). The error terms are either of the form \( \langle 1_y | e^{i\theta} \) corresponding to a pointer shifted in the wrong direction, or of the form \( f(P, |1_y\rangle \) corresponding to the spin not having remained in the state \( |1_y\rangle \). The norm of the error terms is proportional to \( 1/N \), and in the limit of large \( N \) they can be neglected. One then finds that after and during the measurement the spin is still in the eigenket \( |1_y\rangle \) and that the pointer of the measuring device is shifted by the weak value \( \langle \sigma_z \rangle_w = \langle 1_y | \sigma_z | 1_y \rangle / \langle 1_y | 1_y \rangle = -1 \). Thus we confirm that in the limit of large \( N \), the evolution is given by the effective non-Hermitian Hamiltonian.

In this Letter we have analyzed adiabatic measurements on systems which evolve according to an effective non-Hermitian Hamiltonian. The effective Hamiltonian only arises when a partial postselection is realized. For an adiabatic measurement to yield a significantly unusual result, the non-Hermiticity of the Hamiltonian must be
large, and in such cases the probability of a successful partial postselection is very small. There is, however, a reasonable hope of performing such a measurement in a real laboratory. It is conceivable to build an experiment in which the measuring device is a particular degree of freedom of the measured particle itself, and in this case the postselection process is particularly simple [12].
