Dopamine (DA) neurons in the mammalian central nervous system are thought to be restricted to the brain. DA-mediated regulation of urinary activity is considered to occur through an interaction between midbrain DA neurons and the pontine micturition center. Here we show that DA is produced in the rat spinal cord and modulates the bladder reflex. We observed numerous tyrosine hydroxylase (TH) + neurons in the autonomic nuclei and superficial dorsal horn in L6–S3 spinal segments. These neurons are dopamine-β-hydroxylase (DBH) - and some contain detectable dopamine decarboxylase (DDC), suggesting their capacity to produce DA. Interestingly, following a complete thoracic spinal cord injury (SCI) to interrupt supraspinal projections, more TH + neurons emerged in the lumbosacral spinal cord, coincident with a sustained, low level of DA expression there and a partially recovered micturition reflex. Non-selective blockade of spinal DA receptors reduced bladder activity whereas activation of spinal D 2 -like receptors increased bladder activity and facilitated voiding. Additionally, depletion of lumbosacral TH + neurons with 6-hydroxydopamine (6-OHDA) decreased bladder non-voiding contractions and voiding efficiency. Furthermore, injecting the transsynaptic neuronal tracer pseudorabies virus (PRV) into the bladder detrusor labeled TH + cells in the lumbosacral cord, confirming their involvement in spinal micturition reflex circuits. These results illustrate that DA is synthesized in the rat spinal cord; plasticity of lumbosacral TH + neurons following SCI may contribute to DA expression and modulate the spinal bladder reflex. Thus, spinally-derived DA and receptors could be a novel therapeutic target to improve micturition recovery after SCI.

1. Introduction

Dopamine (DA) is an important neurotransmitter modulating a broad range of body behaviors. Disrupting DA signaling results not only in motor dysfunction but also in autonomic disorders (Shulman et al., 2001; Sakakibara et al., 2011). For instance, irritable hyperactive bladder symptoms, such as urinary urgency, frequency, and incontinence, often occur when midbrain DA neurons are damaged in Parkinson’s disease (PD) (Winge and Fowler, 2006). Although the underlying mechanism behind bladder hyperreflexia in PD patients is not completely understood, the degeneration of DA neurons in the substantia nigra and resulting deficiency of D 1 -mediated action upon the pontine micturition center (PMC) are a fundamental cause (Sakakibara et al., 2002; Yoshimura et al., 2003). Interestingly, D 2 -mediated facilitation of micturition has been reported in normal, cerebrally-infarcted, and chemically-induced Parkinsonian animals (Yoshimura et al., 1998; Yokoyama et al., 1999; Seki et al., 2001; Kitta et al., 2012), indicating that DA in regions other than the brain may modulate micturition.

Recent studies revealed that autonomic neurons in the rat lower spinal cord express DA receptors (Gladwell et al., 1999; Stafford and Coote, 2006), suggesting that DA released within the cord helps regulate autonomic function. Though DA neurons are known to reside in the spinal cord of non-mammalian species, e.g. birds and fish (Roberts and Meredith, 1987; Acerbo et al., 2003), they are thought to be restricted to the brain in mammals (Bjorklund and Dunnett, 2007). Thus, DA in the spinal cord is assumed to come from diencephalospinal pathways that originate mainly from the A11 cell group (Skagerberg et al., 1982; Taniguchi et al., 2011; Sharples et al., 2014). Nevertheless, Mouchet and colleagues observed tyrosine hydroxylase (TH) + cells in the rat spinal cord (Mouchet et al., 1986). Since TH is expressed in multiple neuron types, including DA-ergic and adrenergic ones, it is not clear if these neurons synthesize neurotransmitter DA. Moreover, the function of these neurons is unknown. Here, we perceived a similar distribution of TH + cells in the rat spinal cord, confirming the previous observation. The majority of these cells are aggregated in the lumbosacral segments, particularly within the autonomic region and superficial dorsal horn. Importantly, some of them display typical DA-ergic characteristics.

The location of TH + cells in the lumbosacral cord suggests their involvement in pelvic visceral activity, such as micturition. However, the

0014-4886/Published by Elsevier Inc.
presence of A11 DA-ergic and other descending catecholaminergic projections that contain DA as a precursor precludes us from determining what function the spinal TH+ neurons have. To specifically identify if these neurons play a role in urinary function, we used a complete spinal cord injury (SCI) model to remove descending control and retain only spinal micturition neural circuitry. Interruption of supraspinal micturition pathways causes acute areflexic bladder paralysis. Yet, over a few weeks, there is usually a partial recovery of urinary function via involuntary bladder and urethral reflexes (Fowler et al., 2008; de Groat and Yoshimura, 2012). In the present study, we observed remarkable plasticity of lumbosacral TH+ neurons after SCI that contributed to a low level of sustained, local spinal DA expression. Furthermore, spinal DA receptors regulating bladder reflex are active, indicating that this spinalially-derived DA modulates the recovered micturition function.

2. Materials and methods

2.1. Animals

For these experiments, we used 104 adult female (weigh 200–250 g) and 3 postnatal day 10 (P10) Wistar rats, 4 adult female Sprague Dawley (SD, weigh 200–250 g), and 4 adult female Fischer 344 rats (F344, weigh 150–200 g). Wistar rats were employed for both histology and cystometry whereas SD and F344 rats were used for histological comparison. Institutional Animal Care and Use Committee and National Institutes of Health guidelines on animal care were strictly followed to minimize the number of animals used and any potential suffering.

2.2. Spinal cord surgery

Two SCI animal models were used. Because TH+ neurons were observed throughout the length of the spinal cord, we transected the spinal cord at the higher thoracic level (T4) to study injury-induced intraspinal plasticity, as a high level of injury affects a substantial amount of spinal cord tissue below the injury to evaluate bladder function, however, we performed T10-transection to completely remove supraspinal control and partially remove some propriospinal projections onto spinal micturition neuronal circuits as descending propriospinal projections may affect bladder function following SCI. Animals were anesthetized with 2% isoflurane. A partial laminectomy was performed at T3 or T9 vertebra to expose the dorsal spinal cord. The spinal cord was completely transected at T4 (T4–Tx; n = 18) or at T10 (T10–Tx; n = 52) using a No.11 blade. Lesion completeness was verified visually at the time of surgery and histologically following perfusion. Overlying musculature and skin were then closed. Animals were administered Lactated Ringer’s solution (Baxter Healthcare, Deerfield, IL), cefazolin (10 mg/kg), and buprenex (0.1 mg/kg; Reckitt Benckiser) post-operatively. Bladders were manually expressed at least twice daily until sacrifice.

2.3. ELISA for DA

DA expression in the rat lumbosacral spinal cord was examined with a DA ELISA kit (Eagle Biosciences, Nashua, NH). Naïve or T10–Tx rats 1, 3, or 6 weeks after injury (n = 3/group) were euthanized with an overdose of Euthasol and then transcardially perfused with 100 ml ice-cold 0.1 M PBS. The dorsal half of L6–S3 spinal cord (~0.5 cm) was quickly dissected and frozen on dry ice. Samples were sonicated in lysate buffer (PBS with 0.25% Triton X-100, 5 mM EDTA, 0.5% BSA, 1 mM PMSF, and 1 μl/ml aprotinin) (Taylor et al., 2006). ELISA plates were incubated with the samples per manufacturer’s instructions. DA levels between groups were compared using a one-way analysis of variance (ANOVA) followed by Fisher’s PLSD post hoc tests (SPSS).

2.4. Fluorogold injection

To retrogradely label sympathetic preganglionic neurons (SPNs) in the intermediolateral cell column (IML) and parasympathetic preganglionic neurons (PPNs) in the lower lumbosacral cord, naïve rats (n = 6) received an intraperitoneal injection of Fluorogold (FG, 0.4 ml of 0.5% in distilled water; Fluorochrome, Denver, Colorado) (Akhavan et al., 2006). Animals were perfused 1 week later.

2.5. Bladder cystometry

We performed cystometry to assess bladder function in rats with T10–Tx (n = 30) 3 weeks after injury. Naïve rats (n = 6) were used as controls. All rats were anesthetized with isoflurane and an incision was made in the lower abdomen to expose the urinary bladder. The apex of the bladder dome was punctured using an 18-gauge needle. One end of a catheter (PE-60; Clay Adams) was inserted into the bladder (Yoshiyama et al., 1999; Mitsui et al., 2005). The other end of the catheter was tunneled subcutaneously and out the back. The abdominal wall was then sutured closed. To intravenously deliver pharmacological agents, a separate cannula (PE-10) filled with heparinized saline (1000 U/ml) was implanted in the right femoral vein. The peripheral end was connected to a blunt, T-shaped 27-gauge needle.

Immediately after removal of isoflurane, rats were lightly anesthetized with urethane (1.2 g/kg in naïve rats and 0.8 g/kg in SCI rats, i.p.) (Yoshiyama et al., 2013) and placed in a restraining cage (KN-326, Natsume). The bladder catheter was connected to a pressure transducer (Transbridge, WPI) and a microinjection pump (SP2001, WPI). Room-temperature saline was slowly infused into the bladder (0.1 ml/min). Though micturition cycles usually became stable and fairly regular after approximately 30 min of saline infusion, we waited for at least 1 h before starting the recording to allow for ample adaptation time. At least five continuous stable micturition cycles pre- and post-drug delivery were collected per rat. Experiments lasted no longer than 3 h. Urodynamic parameters including the voiding amplitudes of intravesical bladder pressure (VA), the intervals between two sequential voiding events (VI), and the voiding volumes (VV) were measured.

Fig. 1. Cartoon illustrating various urodynamic parameters measured during bladder cystometry. In both naïve (A) and complete SCI (B) rats, the voiding amplitudes of intravesical pressure (VA) are always calculated from the peak of voiding onset to the baseline of bladder activity. The voiding intervals (VI) are defined as the time duration between two continuous voiding onsets. Compared to the voiding behavior in naïve rats (A), spinal bladder reflex in SCI rats (B) displays greater amplitudes of voiding pressure and more variable voiding patterns, based on the extent of spontaneous bladder reflex recovery. Notably, non-voiding bladder contractions (Δ) often occur only in rats with SCI and not in naïve rats.
(Fig. 1). To measure the VV, expelled urine in each voiding cycle was collected into a small plastic box during cystometry. In rats with SCI, the number of non-voiding contractions (NVC) per micturition episode was also calculated. NVC are defined as rhythmic intravesical pressure increases 5 mm Hg from baseline without a release of fluid from urethra (Mitsui et al., 2005). In each rat, the parameter values in 5 voiding cycles were averaged to determine the mean value for statistical analysis. Animals were sacrificed at the end of this experiment.

2.6. Pharmacological interventions of spinal DA receptors

Equivalent volumes of 0.9% saline were delivered intravenously (i.v.) via femoral vein to obtain pre-treatment measurements. Afterwards, DA receptor agonists or antagonists (Tocris Cookson) were given i.v. (Table 1). The doses of the drugs used were chosen on the basis of previously published data (Yoshimura et al., 1998; Seki et al., 2001; Ogawa et al., 2006). All drugs were dissolved in 0.9% saline. Urodynamic data collection was performed within 30 min after drug delivery. The post-drug parameters for each rat, with the exception of NVC, were calculated as a percentage of individual baseline values. To compare normally distributed parameters following saline or single drug application, a paired Student’s t-test was employed. Wilcoxon signed-rank test was used for nonparametric data.

2.7. 6-OHDA injections into L6/S1 spinal cord

To determine the role of lumbosacral TH+ neurons in the spinal bladder reflex, we depleted these cells by injecting the catecholaminergic neurotoxic agent 6-hydroxydopamine (6-OHDA) (Winkler et al., 1996; Kondoh et al., 2005) into the L6/S1 spinal cord. Two weeks after T10–Tx, rats were anesthetized with isoflurane, the L6/S1 spinal cord was exposed by laminectomy and 6 μl of 0.2% 6-OHDA was slowly injected into the tissue using a glass micropipette connected to a Hamilton syringe (3 sites per side, 1.5 mm distance between adjacent injections in each side; coordination: 0.5 mm lateral from the midline, 0.5 and 1.0 mm depth, 0.5 μl per depth; n = 5). Some T10–Tx rats (n = 5) were injected only with saline vehicle. Overlying musculature and skin was closed. One week later, the rats underwent bladder catheterization and cystometry assessments, as described above. Animals were then perfused.

2.8. Pseudorabies virus (PRV) transsynaptic tracing

Naïve (n = 8) or T10–Tx rats 3 weeks after injury (n = 8) were anesthetized. An abdominal incision was made to expose the urinary bladder. PRV-152 (Bartha strain, 10⁶ pfu/ml) encoding for green fluorescent protein (GFP) was slowly injected into the ventral bladder detrusor muscle with a Hamilton syringe (3 sites, 2 μl/site, for a total of 6 μl) (Nadelhaft and Vera, 1995). Injection sites were immediately sealed with a small drop of tissue glue. The incision was closed with sutures. Animals were perfused 48 or 72 h later (n = 4 per group) for histological analysis.

2.9. Histology

2.9.1. Tissue processing

Naïve (n = 12 in adult and 3 in P10 Wistar, 4 in SD, 4 in F344) or SCI animals were overdosed with Euthasol and then perfused transcardially with 0.1 M phosphate buffered saline (PBS), pH 7.4, followed by 4% paraformaldehyde in PBS. Spinal cords were dissected, divided into two 3 cm portions of caudal (T13–S4) and rostral (T5–T12) segments, post-fixed, and cryoprotected. Coronal (20 μm) or horizontal (35 μm) sections were obtained using a cryostat (Cameron et al., 2006) and kept in order. To check for possible TH+ efferents, the ventral efferent nerve roots at L1–S3 levels from naïve (n = 3) and T4–transected (n = 3) adult Wistar rats were dissected and cryosectioned longitudinally (10 μm). Brains of naïve rats (n = 6) were cryosectioned sagittally at 35 μm.

2.9.2. Immunohistochemistry

Spinal cord coronal sections 200 μm apart or longitudinal sections 210 μm apart were used in each immunostaining (Hou et al., 2013). Mounted spinal coronal sections or free-floating longitudinal tissue sections were incubated with primary antibodies diluted in blocking solution (Tris-buffered saline, TBS, containing 5% goat serum and 0.5% triton X-100) overnight at 4 °C. We used primary antibodies against tyrosine hydroxylase (TH, rabbit or mouse, 1:1000, Millipore), dopamine-β-hydroxylase (DBH, mouse, 1:1000, Millipore), dopamine decarboxylase (DDC or AADC, rabbit, 1:1000, Abcam), dopamine transporter (DAT, rabbit, 1:500, Synaptic Systems), choline acetyltransferase (ChAT, mouse, 1:200, Millipore), NeuN (mouse, 1:200, Chemicon), D2-like receptors (rabbit, 1:600, Abcam), D2-like receptors (rabbit, 1:200, Millipore), c-fos (mouse, 1:500, Abcam), GFP (mouse, 1:500, Millipore). Longitudinal sections of ventral nerve roots were incubated with antibodies against TH (rabbit, 1:1000) and TuJ1 (chicken, 1:1000, Aves). Following rinsing, sections were by incubated in Alexa 488 or 594-conjugated goat or donkey secondary antibodies (1:500, Invitrogen) for at least 3 h at room temperature. For immunostaining for TH (mouse), DDC, and DAT, antigen retrieval technique was applied. Sections were incubated with 10% Target Retrieval Solution (Dako) prior to performing standard immunohistochemical procedures, as described. Slides were coverslipped with mounting medium containing DAPI except those labeled with FG. Sections were imaged using a Leica DM5500B microscope and a Leica confocal (TCS SP2).

2.9.3. Quantitative analysis

Quantification was conducted by an observer blinded to group identity. All TH+ cells in the medial gray matter including the lateral parasympathetic nuclei and lamina X around the central canal were counted at 200× magnification in each section of one series of coronal lumbosacral cord sections. Only cells displaying typical neuronal morphology with cellular processes and a DAPI+ nucleus were counted. TH+ cells and TH+/DDC+ cells in the lateral parasympathetic nuclei were counted in one series of longitudinal spinal cord sections. The percentage of TH+/DDC+ cells to the total number of TH+ cells per rat was calculated. In 6-OHDA or saline-injected spinal cords, TH+ neurons were counted in 5 mm-long longitudinal sections containing L6/S1 level. To quantify PRV-152 infected TH+ neurons, a series of coronal L6/S1 spinal cord sections were immunostained for TH and GFP. A total of GFP-labeled cells or GFP+/TH+ cells were then counted in these sections. An unpaired Student’s t-test was used to analyze these data.

3. Results

3.1. Lumbosacral TH\(^+\) cells are interneurons

Two different antibodies for TH immunolabeled many cells in the spinal cord of naïve adult Wistar rats. While these TH\(^+\) cells were present in the gray matter throughout the spinal cord, the majority resided in the L6–S3 spinal segments (Fig. 2A–F), which differs from the previous observation of TH\(^+\) cells mainly at only S1 (Mouchet et al., 1986). These lumbosacral TH\(^+\) cells were distributed in the lateral parasympathetic region, lamina X, and superficial dorsal horn (Fig. 2). Consistent with previous data, spinal TH\(^+\) cells did not co-express dopamine-β-hydroxylase (DBH), the enzyme that converts DA to norepinephrine, strongly suggesting that these neurons were DA-ergic and not adrenergic (Fig. 2B–C, E–F). Their presence was not strain-specific as similar TH\(^+\) populations were seen in adult Wistar, Sprague Dawley, and Fischer 344 rats (data not shown).

To distinguish lumbosacral TH\(^+\) cells and projections from supraspinal catecholaminergic pathways, we transected the thoracic spinal cord of naïve adult Wistar rats. While these TH\(^+\) cells were present in spinal cord at level T4 to completely interrupt these descending fibers, we observed isolated TH\(^+\) cells and projections within the lumbosacral cord (Fig. 2G–J). These prominent TH\(^+\) cells extended axons to the contralateral side or across lumbosacral segments. Long ascending projections were not detected.

The spinal TH\(^+\) cells expressed the mature neuronal marker NeuN, indicating that they are indeed neurons (Fig. 3A). Since the majority of the TH\(^+\) neurons were located in the parasympathetic nuclei, we sought to determine whether they are a yet-to-be described part of the parasympathetic efferent system. Fluorogold (FG) was injected i.p. into intact rats to retrogradely label PPNs. One week later, we found TH\(^+\) cells juxtaposed to FG-labeled PPNs in the lumbosacral cord; no co-localization was detected (Fig. 3B, C). Furthermore, no Tuj1-immunolabeled efferent fibers in L1–S3 ventral roots were also TH\(^+\) (not shown). These results illustrate that lumbosacral TH\(^+\) cells are spinal interneurons and are not parasympathetic efferents.

3.2. Few spinal TH\(^+\) neurons co-express the DA-synthesizing enzyme DDC

The lack of DBH expression in the TH\(^+\) neurons is not sufficient to distinguish if these neurons synthesize DA. To more definitively characterize if spinal TH\(^+\) neurons are truly DA-ergic, we explored whether they express other markers, i.e. the enzyme DDC and the DA transporter (DAT). TH and DDC are both necessary for DA synthesis. TH converts L-tyrosine to L-DOPA. DDC catalyzes L-DOPA to DA, which is then released into the synaptic cleft. DAT is part of the presynaptic regulatory machinery to recapture DA from the extracellular space (Hoffman et al., 1998; Gabriel et al., 2013).

Fig. 2. The distribution of TH\(^+\) cells in the rat lumbosacral spinal cord. A–F. In horizontal sections of the intact rat spinal cord, many TH\(^+\) cells are found in the lateral parasympathetic nuclei (PN) (A), lamina X, and superficial dorsal horn (DH) (D). Though a large number of descending fibers are TH\(^+\) and DBH\(^+\), lumbosacral TH\(^+\) cells and their projections are DBH\(^–\) (B, C, E, F), indicating that they are not noradrenergic/adrenergic. G–I. Three weeks after T4–Tx, spinal TH\(^+\) cells and their processes remain in coronal (G) or longitudinal (H, I) sections of lumbosacral cord. Numerous TH\(^+\) cells are prominent in the parasympathetic regions of gray matter (H, I). TH\(^+\) axons extend segmentally and do not form long ascending projections. J. A schematic diagram illustrates the distribution of TH\(^+\) cells (red) in L6–S3 spinal segments in a transverse view of spinal cord. These subpopulations are connected via fibers in lamina I. Notably, TH\(^+\) cells are intermingled with parasympathetic preganglionic neurons (PPNs, blue) in the lateral autonomic regions. F and I are higher magnifications of regions boxed in E and H. Scale bars: A, B, 75 μm; B, 50 μm; C, 10 μm; E, I, 100 μm; F, 30 μm; G, 200 μm; H, 400 μm.
In the intact spinal cord, a small percentage of TH+ cells were also DDC+ (~4%). They were located in either the lateral autonomic region or the superficial dorsal horn but not in lamina X (Fig. 3F). After T4–Tx, TH+/DDC+ cells were apparent in the autonomic nuclei (Fig. 3F). We also observed a few DDC+/TH− neurons in the dorsal and medial gray matter. Throughout the spinal cord, abundant DDC+ cells were present in the ependymal or subependymal layers of the central canal and many TH+ neurons reside in the neighboring regions (G). A representative TH+/DDC− cell (H), TH+/DDC− (I), or TH−/DDC− (J) neuron in the lumbosacral spinal cord. K. Dopamine transporter (DAT) is not detected in TH+ neurons. L–O. TH+ neurons in the VTA express strong signals of DDC (L) and DAT (M). However, the majority of TH+ neurons in the A11 nucleus do not contain or express very little DDC (N); A11 TH+ neurons do not express DAT (O). Images B–K are from longitudinal spinal cord sections and L–O are from sagittal brain sections. Scale bars: A, 20 μm; B, 100 μm; C, 10 μm. D, G, O, 50 μm; E, 32 μm; J, 12 μm; K, 25 μm.

3.3. Plasticity of lumbosacral TH+ neurons after SCI

As mentioned above, we transected thoracic spinal cord to better visualize the spinal TH+ neurons. Supraspinal TH+ fibers in the dorsolateral funiculus caudal to a T4–Tx lesion site gradually degenerated and were absent by 3 weeks after SCI (Fig. 4A–C). We noticed that there appeared to be more TH+ neurons in the injured spinal cord than in the naive cord. Quantitative analysis confirmed a significantly greater number of TH+ neurons in the parasympathetic region 1 and 3 weeks post-injury (Table 2; Fig. 4D–G). Despite this increase, the percentage of TH+/DDC+ cells to all TH+ cells in the lateral autonomic region did not significantly change (Fig. 3D, G, 4H). Similar results were observed following T10–Tx (data not shown). These data suggest that there is injury-induced plasticity of TH+ neurons in the lower spinal cord.

3.4. DA expression in the spinal cord following SCI

To better assess whether these TH+ neurons produce DA, we measured DA levels in L6–S3 cord in intact and T10–Tx rats using ELISA. Not surprisingly, the level of DA was significantly lower in tissue caudal to a SCI than in the intact because of the interruption and degeneration of descending DA-ergic fibers. The concentration of DA dramatically dropped 1 week after transection (Table 2; Fig. 5; p < 0.001). Notably, a considerable level of DA was still detectable after 3 weeks and persisted at 6 weeks, despite the fact that no supraspinal TH+ fibers were found in the cord at these two time points (Fig. 5C, F). These data demonstrate that DA is indeed synthesized in the spinal cord, even after SCI.

3.5. Pharmacological interventions of spinal DA receptors alter bladder function

Previous studies demonstrated the expression of DA receptors on SPNs in rat spinal cord (Gladwell et al., 1999; Stafford and Coote, 1996). The expression of both types of DA receptors is concomitant with the expression of TH and DDC in the spinal cord. These receptors include DA1 and DA2 receptors. These studies suggest that DA receptors modulate the activity of SPNs.
We also identified both D₁-like and D₂-like receptors on ChAT⁺ or FG-retrogradely labeled lumbosacral PPNs (Fig. 6A–C). Thus, it is possible that spinally-derived DA modulates pelvic autonomic function, such as micturition. To begin to elucidate this, naïve rats were administered (i.v.) with the non-selective DA receptor antagonist flupenthixol during bladder cystometry. This significantly decreased voiding amplitudes of intravesical pressure (VA; \( p < 0.05 \)), shortened voiding intervals (VI; \( p < 0.05 \)), and reduced voiding volumes (VV; \( p < 0.001 \), Fig. 6D, E), suggesting inhibited bladder contraction and decreased bladder capacity.

While these data indicate that DA plays a role in micturition, the effects of silencing DA receptors in either the brain or the spinal cord cannot be separated in the naïve rat. To isolate the effects of spinal DA, we again utilized a complete SCI model to disrupt descending projections. Rats were infused with flupenthixol i.v. 3 weeks after T10–Tx. Antagonizing spinal DA receptors after SCI also significantly decreased VA, indicating an inhibitory effect on bladder contraction. However, unlike in naïve rats, flupenthixol in SCI rats substantially prolonged VI (both \( p < 0.05 \), Fig. 6F, G), which appeared to facilitate bladder continence. Increasing the dose of flupenthixol produced similar responses and even significantly reduced the number of NVC (Fig. 6G; Table 1). These data strongly indicate that spinal DA receptors actively regulate the bladder reflex after SCI.

To further parse out which subtype of spinal DA receptor is responsible for micturition control and if various DA receptors play different roles, we administered specific DA receptor agonists or antagonists in the SCI rats during cystometry. Selective blockade of D₁-like receptors with SCH 23390 significantly increased VA (\( p < 0.05 \)). Other urodynamic parameters measured were not affected (Fig. 7A, C). No response was observed when D₁-like receptors were activated by SKY 38393 (Fig. 7E, G). Administration of quinpirole, an agonist of D₂-like receptors,
increased VA, prolonged VI, and increased VV \((p < 0.05; \text{Fig. } 7\text{~B,~D})\). No effect was observed when D2-like receptors were blocked with a low dose of remoxipride (Fig. 7\text{~F,~H}). These results indicate that following SCI, spinal D1-like receptors are tonically active to affect bladder function; spinal D2-like receptors may be silent but their activation can enhance bladder activity and efficiently increase voiding efficiency.

### 3.6. Ablation of spinal TH\(^+\) neurons reduces bladder activity

Administering the catecholaminergic neurotoxin 6-OHDA into L6/S1 spinal cord of T10–Tx rats effectively reduced the number of TH\(^+\) neurons present there (Fig. 7\text{~I}). There were dramatically fewer TH\(^+\) neurons in rats injected with 6-OHDA than with saline (Fig. 7\text{~J}; \(p < 0.05\)). 6-OHDA mediates-depletion of lumbosacral TH\(^+\) neurons significantly reduced bladder NVC and the voiding volume (Fig. 7\text{~K,~L}), reflecting an inhibition of bladder activity and reduced voiding efficiency. Thus, lumbosacral TH\(^+\) neurons appear involved in spontaneously recovered bladder function and bladder hyperactivity following SCI.

### 3.7. Lumbosacral TH\(^+\) neurons are an active component of bladder reflex circuitry

Additional evidence supports that lumbosacral TH\(^+\) neurons are involved in spinal bladder reflex circuitry. We first examined expression of the immediate early gene c-fos, a marker of neuronal activation (Cohen and Greenberg, 2008), in the lumbosacral spinal cord immediately after cystometry. In both naïve and SCI rats, most TH\(^+\) cells in the parasympathetic nuclei were highly immunoreactive for c-fos (Fig. 8\text{~A}). In another cohort of naïve or T10–Tx rats, we injected the transsynaptic tracer pseudorabies virus (PRV-152) into the bladder detrusor. After 48 h in the naïve rat, some PPNs in the L6/S1 spinal

**Fig. 5.** A low level of DA expression sustains in the lumbosacral spinal cord after SCI. DA expression in the dorsal half of L6–S3 spinal segments was measured by ELISA in the intact or T10–Tx spinal cord. DA levels significantly decrease 1 week following injury (one-way ANOVA, followed by Fischer’s LSD, ***\(p < 0.001\)). After 3 weeks, however, an appreciable level of DA (approximately 10% of baseline level) is still detected, even though supraspinal TH\(^+\) projections below the lesion have completely degenerated. This low level of DA expression persists in 6 weeks post-injury and is not significantly different than levels found 3 weeks after SCI.

**Fig. 6.** Non-specific blockade of spinal DA receptors inhibits bladder activity in SCI rats. **A-C.** Lumbosacral parasympathetic preganglionic neurons (PPNs) express D1-like and D2-like receptors. ChAT\(^+\) spinal PPNs (\(A\)) express D2-like receptors (\(B\)) in a longitudinal section of spinal cord. C. Lumbosacral PPNs retrogradely labeled by i.p. injections of Fluorogold (FG) express D1-like receptors. **D-G.** Representative traces of bladder cystometry in intact (\(D\)) or T10–Tx rats (\(F\)) after i.v. administration of the non-selective DA receptor antagonist flupenthixol. Inactivating DA receptors significantly reduces VA, VI, and VV in naïve rats (\(E\)), but decreases VA and increases VI in SCI rats 3 weeks post-injury (\(G\); repeated measures of one-way ANOVA followed by paired t-test, \(*p < 0.05\), \(**p < 0.01\), \(****p < 0.001\)). This suggests that DA receptors in the lower spinal cord are active and spinally-derived DA modulates bladder activity following SCI. All parameter values (with saline or drugs) were normalized as a percentage to the baseline (red arrowheads represent drug delivery; green asterisks mean voiding). Scale bars: \(A\ 200 \mu m; \(B, C) 20 \mu m.\)
cord were GFP+, yet very few TH+ neurons co-expressed GFP (Table 2; Fig. 8B, F). After 72 h, more GFP+/TH+ neurons were seen in the autonomic region (Fig. 8C, F). In the injured spinal cord, we found significantly more GFP+/TH+ neurons in the region at both 48 h (Fig. 8D, F) and 72 h (Fig. 8E, F) after PRV injections than in the intact condition (p < 0.05). We saw a similar injury-induced increase in the

Fig. 7. Pharmacological interventions of specific spinal DA receptors or ablation of TH+ neurons interfere with recovered bladder function. A–H. Three weeks after T10–Tx, (A, C) administration of the specific D1-like receptor antagonist SCH 23390 significantly increases VA but does not affect any other cystometric parameters (paired t-test, *p < 0.05). (B, D) Delivery of quinpirole, a specific D2-like receptor agonist, significantly increases VA, VI, and VV (paired t-test, *p < 0.05). However, neither (E, G) selectively activating D1-like receptors with SKF 38393 nor (F, H) blocking D2-like receptors with remoxipride significantly affects any measured parameters (paired Student's t-test, all p > 0.05). I–L. Depletion of lumbosacral TH+ cells inhibits spontaneously recovered bladder function after SCI. (I, J) After 6-OHDA injections into the L6/S1 spinal cord, the number of local TH+ cells is dramatically less when compared to control rats that received saline injections (unpaired t-test, *p < 0.05). (K, L) Bladder cystometry shows that those received 6-OHDA injections exhibit remarkably fewer NVC and reduced VV. No differences in VV or VI between groups were observed (nonparametric Wilcoxon rank-sum test, *p < 0.05, **p < 0.01; arrowheads indicate when drugs were delivered; asterisks indicate when voiding occurred).
seen in both intact (B) or injured (E) cord are labeled with GFP (arrow in E); 72 h post-inoculation, some GFP-labeled TH+ neurons (arrows) can be seen in both intact (C) and injured (F) spinal cords. The inset is a high magnification of a double-labeled neuron. D. Quantitative analysis shows that there are significantly more GFP+/TH+ neurons in the injured cord than in the intact one at either 48 h (unpaired Student’s t-test, "p < 0.05") or 72 h after PRV injection. G–I. In a postnatal day 10 rat, immunolabeling reveals many TH+ neurons (arrows) and fibers in a coronal section of the lower spinal cord (G). Prominent TH+/DBH+ neurons are located in the lateral parasympathetic nuclei (PN, H) and lamina X (I), suggesting that spinal TH+ neurons may be associated with pelvic visceral activity during development. All images are from coronal sections. cc, central canal. Scale bars: A, I, 20 μm; F, 35 μm; G, 350 μm; H, 30 μm.

**Fig. 8.** TH+ neurons are involved in the spinal bladder reflex circuitry. A. After cystometry assessment, some lumbosacral TH+ neurons express the immediate early gene c-fos, a marker of related neuronal activity. B–F. PRV-152 was injected into the bladder wall of intact or T10–Tx rats. After 48 h, some parasympathetic preganglionic neurons (PPNs) in the L6/S1 spinal cord are labeled with GFP. Very few TH+ neurons in the intact (B) or injured (E) cord are labeled with GFP (arrow in E); 72 h post-inoculation, some GFP-labeled TH+ neurons (arrows) can be seen in both intact (C) and injured (F) spinal cords. The inset is a high magnification of a double-labeled neuron. D. Quantitative analysis shows that there are significantly more GFP+/TH+ neurons in the injured cord than in the intact one at either 48 h (unpaired Student’s t-test, "p < 0.05") or 72 h after PRV injection. G–I. In a postnatal day 10 rat, immunolabeling reveals many TH+ neurons (arrows) and fibers in a coronal section of the lower spinal cord (G). Prominent TH+/DBH+ neurons are located in the lateral parasympathetic nuclei (PN, H) and lamina X (I), suggesting that spinal TH+ neurons may be associated with pelvic visceral activity during development. All images are from coronal sections. cc, central canal. Scale bars: A, I, 20 μm; F, 35 μm; G, 350 μm; H, 30 μm.

percentage of total GFP+ cells that were also TH+ in SCI rats compared to naïve rats at either 48 h or 72 h (both p < 0.01) post-PRV injection (Table 2). These results suggest the involvement of TH+ neuron plasticity in the reestablished spinal bladder reflex pathways.

Discussion

The principal source of DA in the mammalian spinal cord is considered to be the A11 cell group in the diencephalon. Their axons mainly terminate in the dorsal horn, IML, and lamina X (Skagerberg et al., 1982). Here, we report that spinal TH+ neurons are another source of DA in the spinal cord. Interestingly, these cells are predominantly located near where A11 projections terminate in the lower cord. Moreover, they are phenotypically comparable to the TH+ neurons in A11. These TH+ interneurons in the autonomic region make functional synaptic contacts upon PPNs. Following SCI, plasticity of lumbosacral TH+ neurons is correlated to the reestablishment of spinal bladder reflex pathways and appears to at least partly regulate spontaneously recovered urinary function.

DA is still detected below a complete spinal cord transection, supporting the notion that DA is also produced in the spinal cord. TH and DDC are two enzymes necessary to synthesize DA. We observed not only TH+/DDC+ bienzymatic neurons but also TH+ or DDC+ monoenzymatic neurons residing in the rat spinal cord. Bienzymatic neurons that do not contain DBH are clearly DA-ergic (Ershov et al., 2002). While we cannot completely exclude the possibility that DDC is expressed at a level below our detection in the neurons we described as TH+/DDC−, these cells may still have the capacity to produce DA, even if truly monoenzymatic. Indeed, DA neuron phenotypes are more complex than originally thought. Besides “canonical DA-ergic neurons” which possess both enzymes needed for DA synthesis (i.e. TH and DDC), studies have described neurons that express only one or the other (Ershov et al., 2002; Karasawa et al., 2007). As a matter of fact, TH+ or DDC+ monoenzymatic neurons are widely distributed throughout the brain in adulthood. These two classes of neurons can cooperatively synthesize DA, that is to say, TH+ cells convert L-tyrosine to L-DOPA; L-DOPA is then released and taken up by the DDC+ neurons, which convert L-DOPA to DA. This is considered to be a compensatory reaction to the failure of bienzymatic neurons in certain neurological disorders (Ugrumov, 2009). Therefore, it might be unnecessary for a DA neuron to possess a full complement of enzymes required for DA synthesis. In adult rat spinal cord, abundant DDC+ neurons were recently disclosed not only near the central canal, but also in the intermediate zone and dorsal gray matter (Jaeger et al., 1983; Wienecze et al., 2014). Further observations revealed that sacral DDC+ neurons began to produce monoamines after SCI (Wienecke et al., 2014). That we found monoenzymatic TH+ or DDC+ neurons adjacent to each other around the central canal may indicate DA synthesis in the spinal cord via this
two-step mechanism. Moreover, both spinal cord and A11 TH+ neurons do not express DAT, implying that these two populations use an alternative means to regulate extracellular DA levels (Ciliax et al., 1999).

Spinal interneurons are critical for the micturition reflex in neonatal rats and spinal cord-injured rats. During the first 3 weeks after birth, when supraspinal projections have not yet reached spinal target neurons, rats use an interneuron-mediated, spinal bladder reflex pathway to elicit micturition (Araki and de Groat, 1997). Interneurons in the lumbar spinal cord receiveafferent input from the lower urinary tract and form excitatory or inhibitory synapses with PPNs involved in the regulation of micturition (de Groat and Yoshimura, 2012). As the animal continues to mature, supraspinal pathways gradually dominate bladder function. Descending axon innervation and synaptic reorganization in the spinal autonomic nuclei eventually leads to the elimination of primitive segmental reflexes and the emergence of mature spinobulbospinal reflexes (Araki and de Groat, 1997; Miura et al., 2003). Following SCI interrupting supraspinal control, a spinal micturition reflex develops due to intraspinal plasticity. This may arise because of newly-formed spinal circuits or a re-emergence of developmental reflex pathways (Zinck and Downie, 2006). Based on our observations, it appears that lumbar spinal TH+ neurons are essential for this. The number of TH+ cells substantially increased when diencephalospinal DA-ergic pathways were interrupted, coinciding with the time frame of partial recovery of bladder function. Furthermore, chemical depletion of these neurons reduced bladder hyperactivity and voiding efficiency. Thus, we posit that spinal TH+ neurons are a remnant of spinal circuits involved in pelvic visceral activity during development. In fact, we found numerous TH+ neurons and fibers in the autonomic region of lumbar spinal cord in postnatal day 10 rats. While these neurons may not be a key part in micturition regulation in the naïve adult, after the SCI-induced loss of supraspinal DA-ergic control, they undergo plasticity and seem to play a larger role in urinary function.

Our data supports the concept that DA modulation of micturition occurs at both supraspinal and spinal levels. In naïve rats, non-selective blockade of DA receptors with flupenthixol shortened voiding intervals. This result is similar to the symptoms of increased urinary frequency and incontinence in PD patients (Araki et al., 2000). The role of spinally-derived DA in micturition, which acts upon spinal DA receptors, was elucidated by delivering DA receptor agonists or antagonists after a complete thoracic SCI. Non-selective antagonizing DA receptors with flupenthixol inhibited bladder activity, specifying that spinally-derived DA regulates micturition reflex after the loss of descending pathways. The reduction of NVC indicates that spinal DA contributes to SCI-induced bladder hyperactivity. The different actions of DA on bladder reflex are mediated through different DA receptors. In neurologically intact rats, D1-like receptors exert a tonic inhibitory action on the micturition reflex; D2-like receptors do not have tonic activity and their activation facilitates voiding (Yoshimura et al., 1993; Seki et al., 2001; Ogawa et al., 2006). In rats with SCI, spinal cord D1-like receptors appear to exert a tonic inhibitory activity as well, since the selective blockade with SCH 23390 enhanced the bladder activity. Specifically stimulating D1-like receptors had no effect, likely because they were already tonically active (Yoshimura et al., 2003). This illustrates that spinally-derived DA maintains D1-mediated tonic inhibition after removal of supraspinal DA control. On the other hand, activation of spinal D2-like receptors in SCI rats facilitated the bladder reflex whereas suppression with a low dose of a D2 antagonist did not affect any cystometric parameters, similar to what has been observed in naïve rats (Seki et al., 2001). The discrepancy is that non-selectively inhibiting DA receptors with flupenthixol elicited significantly decreased VA and increased VI whereas selectively inhibiting either D1- or D2-like receptors did not induce the same results. As only one dose was chosen for each drug (based on successfully used doses in rats), it is very possible that the discrepancy is dose-dependent. This will be important to follow up in future experiments. Furthermore, given that the sensitivity of spinal DA receptors may be up-regulated following SCI, it will also be important for later studies to assess relative levels of DA receptors on lumbar spinal autonomic neurons and further elucidate how they shape partial recovery of micturition.

Under normal conditions, effective micturition is achieved by coordinated activity of the bladder detrusor and the external urethral sphincter (EUS) via spinobulbospinal reflex pathways. During voiding, the bladder detrusor contracts while the EUS phasically relaxes, resulting in virtually complete expulsion of urine stored in the bladder. After SCI, disruption of supraspinal inhibitory input to motor neurons controlling the EUS increases tonic activity and decreases phasic activity of the muscle. Additionally, the bladder is overactive when descending projections no longer controls lumbar spinal autonomic neurons. As a result, there is a loss of coordination of EUS and bladder detrusor activity and the two muscles can contract simultaneously, a disorder known as detrusor-sphincter dysynergia (DDSD) (Cheng and de Groat, 2004). DSD leads to reduced voiding efficiency and urinary retention. Previous studies demonstrated that D1-like receptors tonically regulate EUS function in the intact rat while activation of D2-like receptors reduces its contraction to assist voiding (Ogawa et al., 2006). Though we found DA derived from the spinal cord elicits D1-mediated control of the bladder detrusor, it is not yet known if the same mechanism mediates increased tonic activity of the EUS after SCI or whether activation of spinal D2-like receptors increases EUS bursting. Thus, we will focus on answering these questions in the subsequent experiments. In addition, we used only one dose of most DA receptor agonists and antagonists to assess the function of these receptors following SCI. To more comprehensively illuminate each of their roles and how they shape the cumulative response, we will repeat these experiments with different drug concentrations and combinations. One of the striking results presented here is the increased number of neurons expressing TH in the lumbar spinal cord after SCI. What is the source of these new TH+ neurons? Previously, more TH+ neurons were observed in the striatum following ablation of DA neurons within the substantia nigra in non-human primates. This was attributed to a putatively shift of GABA-ergic interneurons and not neurogenesis (Tande et al., 2006). A similar mechanism may mediate the increase of spinal TH+ neurons after SCI. This will be explored in future experiments. It is possible that lumbar spinal DA neurons modulate other pelvic organ functions, as a dysfunctional DA system results in abnormal sexual and bowel function and visceral pain (Shulman et al., 2001; Sakakibara et al., 2011; Jarcho et al., 2012), and is therefore valuable for researchers to pursue.

In conclusion, these experiments demonstrate that DA is synthesized in the rat spinal cord. Plasticity of lumbar spinal TH+ neurons may account for the low level of DA expression after SCI. We have identified that spinally-derived DA regulates a recovered bladder reflex in SCI rats. Since multiple neurotransmitters are known to help control micturition (Yokoyama et al., 1999, 2001; Chang et al., 2007), targeting the spinal DA circuits, alone or in combination with other neurotransmitter systems, such as glutamate and serotonin, may prove to be a therapeutic approach to improve micturition and other pelvic functions after SCI.

Author contributions

S.H., V.J.T., and J.D.H. designed the experiments. S.H., D.M.C., D.W., and M.C.K. carried out the experiments. S.H. and D.M.C. analyzed the data and prepared the figures. S.H., V.J.T., and J.D.H. wrote the paper. V.J.T. and J.D.H. oversaw the project.
