Adolescence

ABSTRACT

Social anxiety is prevalent in adolescence. Given its role in maintaining fears, reducing social avoidance through cognitive reappraisal may help attenuate social anxiety. We used fMRI-based neurofeedback (NF) to increase ‘adaptive’ patterns of negative connectivity between the dorsolateral prefrontal cortex (DLPFC) and the amygdala to change reappraisal ability, and alter social avoidance and approach behaviours in adolescents. Twenty-seven female participants aged 13–17 years with varying social anxiety levels completed a fMRI-based NF training task where they practiced cognitive reappraisal strategies, whilst receiving real-time feedback of DLPFC-amygdala connectivity. All participants completed measures of cognitive reappraisal and social approach-avoidance behaviour before and after NF training. Avoidance of happy faces was associated with greater social anxiety pre-training. Participants who were unable to acquire a more negative pattern of connectivity through NF training displayed significantly greater avoidance of happy faces at post-training compared to pre-training. These ‘maladaptive’ participants also reported significant decreases in re-appraisal ability from pre to post-training. In contrast, those who were able to acquire a more ‘adaptive’ connectivity pattern did not show these changes in social avoidance and re-appraisal. Future research could consider using strategies to improve the capacity of NF training to boost youth social-approach behaviour.

Social anxiety is common in young people (Beesdo, Knappe, & Pine, 2009). Normative social fears and concerns arise across adolescence (Sumter, Bokhorst, & Westenberg, 2009) and clinically-impairing social anxiety is often also first diagnosed during this transitional period (Beesdo et al., 2009). Socially-anxious young people often avoid feared social situations (Miers, Blote, Heyne, & Westenberg, 2014). Indeed, self-reported questionnaires and experimental tasks such as the approach-avoidance task (AAT; Rinck & Becker, 2007) indicate greater social withdrawal and avoidant behaviours in socially-anxious adults (Heuer, Rinck, & Becker, 2007) and adolescents (Klein, Becker, & Rinck, 2011). Behavioural avoidance, while reducing short-term feelings of anxiety to negative social evaluation, can be a maladaptive long-term coping mechanism (Aldao, Nolen-Hoeksema, & Schweizer, 2010), detrimental to academic, personal and social development (Rao et al., 2007). This is because it prevents any natural extinction of fears that may occur through exposure, instead allowing individuals to attribute the non-occurrence of feared outcomes to safety behaviours and restricting the opportunity to challenge irrational interpretations of the event (Mcmanus, Sacadura, & Clark, 2008). Managing social anxiety in adolescence thus involves reducing avoidance of social stimuli (Silverman et al., 1999).

Boosting cognitive reappraisal ability to reduce social avoidance in adolescents is a viable strategy (Lisk, Pile, Haller, Kumari, & Lau, 2018). Throughout development, individuals learn to appraise social information, and by adolescence, individual differences in the endorsement of negative versus benign/positive interpretations of ambiguous events is
known to consistently influence (social) anxiety symptoms (Haller, Raeder, Scerif, Kadosh, & Lau, 2016; Stuijfzand et al., 2018) and behavioural tendencies of avoidance (Garfeske, Legerstee, Kraaij, Van Den Kommer, & Teerds, 2002; Garfeske, Van Den Kommer et al., 2002; Hofmann, Heering, Sawyer, & Asnaani, 2009). While cognitive techniques developed to shift emotional appraisals, from focusing on negative explanations and outcomes to alternative benign/positive ones) can reduce social avoidance and/or increase social approach (Narr & Teachman, 2017), implementing these techniques in youth through training has elicited more mixed findings (Cristea, Mogosanu, David & Cuijpers, 2015) (Krebs et al., 2018), underscoring a need for alternative methods to boost their effects.

One approach is to target the neural substrates of cognitive reappraisal. Extensive human work suggests that while the amygdala plays a key role in fear and salience processing (Adolphs, 2002), areas of the prefrontal cortex (PFC) are proposed to have a top-down, regulatory role in relation to amygdala activation by deploying cognitive strategies such as reappraisal (Ochsner & Gross, 2005). In particular, negative patterns of correlated activity between (increased) lateral PFC and (decreased) amygdala activity have been demonstrated in psychiatrically-healthy individuals during tasks involving emotion regulation (ER), including cognitive reappraisal (Ochsner, Bunge, Gross, & Gabrieli, 2002). In contrast, weaker patterns of negative correlations between these regions associate with various psychiatric disorders, including anxiety in adults and social anxiety in adolescents (Prater, Hosanagar, Klumpp, Angstadt & Luan Phan, 2013) (although different patterns of perturbations in amygdala-PFC connectivity have sometimes been found in anxious adolescents; Gold et al., 2016). Regardless, boosting stronger patterns of “negative connectivity” between these regions that resemble those of psychiatrically-healthy adults (rather than anxious adults) could benefit cognitive reappraisal; indeed this circuitry is altered following reappraisal (Goebel, 2014). The suitability of this approach to modulate the underlying networks in psychiatrically-healthy adults (rather than anxious adults) could benefit cognitive reappraisal, and social anxiety in adolescents (Prater, Hosanagar, Klumpp, Angstadt & Cuijpers, 2015) (Krebs et al., 2018), underscoring a need for alternative methods to boost their effects.

1. Methods

1.1. Participants and procedures

This study was registered as preclinical trial #NCT02463136. Forty-six female participants (mean age = 15.09 years; SD = 1.18 years; range: 13–17 years) were recruited from local schools in Oxfordshire. Nineteen of the initial 46 participants received other NF implementations (positive or non-weighted negative) as described in (Zich et al., 2020). Therefore this report focuses on the 27 participants (mean age = 15.22 years; SD = 1.22 years; range: 13–17 years) who received real-time feedback of negative patterns of functional connectivity between the amygdala and DLPCF. All participants had normal or corrected-to-normal vision and no self-reported history of neurological and psychiatric disorders. This study was approved by the Oxford University Research Ethics Committee. Informed consent and assent were obtained from the primary caregiver or young person themselves. Participants completed self-reported questionnaires on social anxiety and emotion regulation, before completing the AAT. They were then prepared for fMRI scanning and provided with instructions for the in-scanner tasks. To identify key emotion regulation regions of the brain to be used in the NF task, a reappraisal task (“localiser”) was conducted inside the scanner. Following this, the NF training was completed. The participant then left the scanner and repeated the AAT, followed by a full debrief. Participants received gift vouchers for taking part.

1.2. Measures

1.2.1. Social anxiety (pre-training only)

Participants rated social anxiety symptoms using the 22-item Social Anxiety Scale for Adolescents (SAS-A; La Greca & Lopez, 1998), a 22-item self-report measure. Each item is (e.g. ‘I worry about doing something new in front of others’) is rated on a 5-point Likert-scale from 0 (not at all) to 5 (all the time). Internal consistency was $\alpha = 0.81$.

1.2.2. Cognitive reappraisal (pre and post-training)

Two items from the Cognitive Emotion Regulation Questionnaire patterns influence anxiety-relevant behaviours outside the scanner, such as social avoidance. The current study investigates whether the provision of feedback on patterns of connectivity between the amygdala and DLPCF can affect socially-avoidant behaviours in adolescents. Given individual differences in the degree to which these co-activation patterns can respond to fc-NF (i.e. become more negative), the primary hypothesis is that, amongst those who are responsive to training, there should be a significant reduction in socially-avoidant behaviours, and significant improvement in cognitive reappraisal ability. However, given prior findings of weaker (negative) functional connectivity of the amygdala and DLPCF in socially-anxious individuals (Prater et al., 2013), we also tested whether there would be associations between social anxiety symptoms and socially-avoidant behaviour with these co-activation patterns at baseline. To index socially-avoidant behaviour, we used the AAT (Rinck & Becker, 2007). The AAT requires the participant to engage in fast approach and avoid actions to social stimuli (emotional faces) via a joystick. Reactions times across different task conditions index the degree to which individuals avoid socially-aversive stimuli and approach socially-appetitive stimuli (Phaf, Mohr, Rotteveel, & Wicherts, 2014) with socially-anxious individuals showing a greater tendency to avoid emotional faces than non-socially-anxious individuals (Heuer et al., 2007; Roelofs et al., 2010). As well as probing individual differences in social anxiety (Rinck et al., 2009), the AAT has also been used in studies to measure changes in social approach/avoidance following neuroendocrine challenges (Enter, Spinboven, & Roelofs, 2014) and psychological manipulations (Vonken, Rinck, Deckers, & Lange, 2012), as well as more specifically, interventions inducing different interpretational styles (Lange et al., 2010).
(CERQ; Garnefski & Kraaij, 2006) assessed cognitive reappraisal (“I think I can learn something from the situation”, “I think that I can become a stronger person as a result of what has happened”). Items were rated on a 5-point Likert scale ranging from 1 ((almost) never) to 5 ((almost) always).

1.2.3. Approach avoidance task (pre and post-training)

The AAT (Rinck & Becker, 2007) tests automatic behavioural avoidance tendencies to emotional faces (Fig. 1). Participants were asked to react to a single picture on the centre of the screen (an adult face with either a happy or angry expression, and a gaze of either straight or averted left/right), by pulling or pushing a joystick (with their dominant hand) in the instructed direction, as quickly and accurately as possible. Upon movement of the joystick, the picture grew or shrunk in size (depending on push or pull) creating the impression of movement towards (approach) or away (avoidance). When the joystick reached 30° in the intended direction the picture disappeared and the joystick had to be returned to the centre position and the ‘fire’ button pressed for the next trial to begin. The task consisted of two blocks of 64 trials (each block preceded by 18 practice trials). In the congruent block, participants were instructed to pull happy faces toward them and push angry faces away, whereas in the incongruent block, participants pushed away happy faces and pulled angry faces towards them. The block order was counterbalanced across participants. Reaction times (RTs) were recorded. For data analysis, time between stimulus onset and the maximum joystick displacement (30°) was used (Radke, Roelofs, & de Bruijn, 2013). Trials in which participants moved the joystick to maximum joystick displacement in the incorrect direction were recorded as errors.

1.3. fMRI tasks

1.3.1. Image acquisition

FMRI data acquisition was performed using a 3 T Siemens MAGNETOM Prisma MRI scanner (Siemens AG, Erlangen, Germany) using a standard 32-channel head matrix coil. Prior to the functional tasks a high-resolution structural volume was obtained from each subject using a T1-weighted magnetization-prepared rapid-acquisition gradient echo

Fig. 1. Graphic representation of the Approach Avoidance Task with angry faces.
(MPRAGE) sequence (TR = 1900 ms, TE = 3.97 ms, FoV = 192 × 192 mm², flip angle = 8°, slice thickness = 1 mm, sagittal). Functional measures comprised the localizer task and four NF training runs. The localizer comprised 570, and each NF run 310, 2D multiband gradient echo planar imaging volumes (Todd et al., 2016) (2.0 × 2.0 × 2.0 mm voxels, 0.57 mm gap, TR = 933 ms, TE = 33.40 ms, FoV = 192 × 192 mm², flip angle = 64°, 72 slices, Multi-band factor = 6, fat saturation, transverse slices with phase encoding in the A -> P direction). To avoid saturation effects, 10 additional volumes were acquired but not analysed at the beginning of the localizer task and each NF run.

1.3.2. Localiser task
A reappraisal task (Fig. 2; Haller et al., 2016) was used to train the individual with cognitive reappraisal strategies and prompt activation of specific brain regions involved in emotion regulation for use in the NF task. During each trial, participants were shown a picture of a social scene from the perspective of a female adolescent approaching the scene, depicted from the back. Each scene connoted themes of negative peer evaluation (appraisal event), which the participant was instructed to appraise freely. Following appraisal, the participant was presented with a positively valanced explanation of the scene. Participants were then shown the scene again and asked to attempt to re-interpret it in the direction of the explanation (reappraisal). This was repeated for 30 trials, with an inter-trial interval displaying a fixation cross for 0.93 s. The task lasted a total of 9 min. Based on the brain activity maps yielded from this task, regions involved in emotion regulation were selected for participant feedback during NF training.

1.4. Neurofeedback training
NF training comprised four runs, each lasting 4.8 min (Fig. 3). Each run started with a fixation cross in the centre of the screen for 18.66 s, which the participant was instructed to focus their attention on. During each run the participant received seven blocks of NF (each lasting 18.66 s), during which they saw continuous feedback of brain activity via a simple picture of a ‘10-point thermometer’.

The number of segments filled in provided the participant with real-time indication of the functional-connectivity between the target regions first defined using the localiser task; this was the negative partial correlation between DLPPC and amygdala relative to an unrelated brain region (a white matter region of the left corticospinal tract). Participants were given the following instructions: “You will see a thermometer with a green rim on the screen. The red bars show how much the regions that are important for emotions are active. Your job is to get these regions as active as possible! So, try to get this thermometer up as much as possible. Similar to the task before, try to control your thoughts towards a positive feeling. When the thermometer does not have a green rim, the thermometer is not working. However, even if the thermometer is not working, your task will be the same and we are still measuring how much your brain is active. The two different thermometers will alternate.” Participants also received seven no-NF blocks in each run, during which participants were asked to continue with the same strategies they were using during the NF blocks, but that the thermometer would be frozen at point six. NF and no-NF blocks were presented in alternating order. To allow participants to differentiate between NF and no-NF blocks, the thermometer in the NF runs was presented with a green frame around it, whereas during the no-NF blocks this frame was missing.

1.5. Statistical analysis plan
1.5.1. AAT data cleaning and extraction
As per previous research using the AAT (Heuer et al., 2007; Marsh, Ambady, & Kleck, 2005; Roelofs et al., 2010), RT outliers were filtered using lower and upper cut-offs of 150 ms and 1500 ms, respectively. Following this, a cut-off of three standard deviations from the mean was used to remove outliers. Incorrect responses were also removed. 91.4% of responses remained, for which medians were calculated per cell (defined by Emotion, Gaze and Action). No differences between conditions were observed for error rates. As per previous studies (Enter et al., 2014; Heuer et al., 2007; Roelofs et al., 2010), effect-scores were calculated as an index of approach/avoidance tendencies. These were calculated by subtracting the mean RTs for pull movements from the mean RTs for push movements for each emotion per individual. Therefore, negative effect-scores indicate stronger avoidance tendencies and positive effect-scores indicate stronger approach tendencies for each emotion. As there were no significant differences between straight and averted gaze conditions for each Emotion (all t’s < 0.23, and all p’s > 0.82), we combined mean RTs for each gaze direction across Action-Emotion combinations.

1.5.2. fMRI functional connectivity data processing
Full MRI data processing and analysis are described by (Zich et al., 2020). In brief, functional images obtained during the localiser task and
the NF runs were processed in real-time using Turbo-BrainVoyager 3.2 (Brain Innovation, Maastricht, The Netherlands). After correcting for head motion and smoothed, three a priori defined ROIs (voxel size = 12 mm$^3$, 6 × 6 × 6) based on the localiser task were manually placed. ROIs were based on a group average activation ascertained from an independent contrast (and therefore did not vary across individuals). GLM t-statistics of the brain activity during the localizer task, i.e. the sum of the three contrasts: appraisal > fixation, reappraisal > fixation, reappraisal > appraisal (threshold t = 3), was projected onto the processed structural scan. The local maximum of the t-statistics within the left dorsolateral and medial PFC constituted the centre of the PFC ROI. Similarly, the local maximum of the t-statistics within the left amygdala constituted the centre of the amygdala ROI. A ROI in the left corticospinal tract (CST) served as control ROI. During the NF task, PFC-amygdala fc was calculated in real-time. PFC-amygdala fc was defined as the partial correlation between PFC and amygdala activity, while controlling for CST ‘activity’. Partial correlations were based on a moving window, which was updated with every incoming volume. The length of the correlation window was 20 volumes. Calculations were performed using a custom-made plugin for Turbo-BrainVoyager, which also provided a direct TCP/IP based link between the real-time analysis software and the stimulus application BrainStim.

Initial functional connectivity for each participant was defined as the average partial correlation of the first two blocks of the first NF run (as described by Zich et al. [2020]). To determine which participants were able to acquire an adaptive pattern of connectivity in response to NF training versus those who were not, we created a training direction variable. This was quantified as the slope of the linear regression for average functional connectivity (i.e. the partial correlation between DLPFC and amygdala relative to a white matter region of the left corticospinal tract), from runs 1 to 4 for each participant. Using this slope variable, we divided participants into those who had a gradient of increasingly negative connectivity across runs (average slope = −0.023, SD = 0.019, range: 0.058 to −0.000058) as those who were able to acquire an adaptive pattern (n = 13) and participants who had a gradient of increasingly positive connectivity across runs (average slope = −0.031, SD = 0.025, range: 0.0091 to 0.079) as those who acquired a maladaptive pattern (n = 14). As one participant from the ‘adaptive’ group had a slope value close to zero (−0.000058), this could reflect difficulties in attaining the desired pattern of connectivity – which in turn could dilute any changes in socially-avoidant behaviour in this group. Removal of this participant from our key analysis, however, did not alter the pattern of results.

1.5.3. Statistical analysis

To assess the validity of the AAT, we tested whether approach-avoidance tendencies toward each emotion (Angry/Happy), pre-NF, were in the predicted direction. To do this, we conducted a two-way repeated-measures analysis of variance (ANOVA) with Action (Pull/Close) and Emotion (Angry/Happy) as the within subject variables. Next, we investigated whether these behaviours were associated with social anxiety by calculating correlations between AAT effect scores for each emotion and SAS-A scores at pre-training. To test the hypothesis that there would be associations between social anxiety symptoms and socially-avoidant behaviour with less negative amygdala-DLPFC co-activation patterns, we calculated the correlation between initial functional connectivity (FC) and social anxiety scores and AAT effect scores pre-NF. To evaluate if there was a significant reduction in socially-avoidant behaviours, the effects of training direction group on changes in AAT effect scores were analysed in a 2 × 2 × 2 mixed ANOVA, with Time (pre, post) and Emotion (happy, angry) as within-subjects variables and training direction group (adaptive, maladaptive) as the between-subject variable. To examine changes in positive reappraisal from pre to post-NF, depending on training direction group, reappraisal scores at pre and post-NF were analysed with a mixed ANOVA of group direction variable (adaptive, maladaptive) and time (pre, post). In all analyses, we controlled for age.

Of note, all analysis conducted on pre-NF variables were done with 45 participants, as one participant was excluded from analysis due to RTs on the AAT deviating over three standard deviations from the group mean. Initial FC data was unable to be collected for 6 participants, therefore all analysis conducted with initial FC was performed with 40 participants. Any analysis assessing changes as a function of NF training were conducted using the 27 participants who received real-time feedback of negative patterns of functional connectivity between the amygdala and DLPFC. The excluded AAT participant was within this group, thus all analysis of NF effects on AAT performance was conducted with 26 participants. In all analyses, alpha was set at 0.05, and effect sizes are reported as partial eta-squared ($\eta^2_p$) or cohen’s d. Bonferroni adjustment controlled for type 1 error in analyses where multiple ANOVAs were conducted, with adjusted p-values reported.

2. Results

2.1. AAT performance and correlations with social anxiety

The mean SAS-A score across participants was 50.11 (SD = 14.18). Fig. 4 shows the mean RTs for each emotion-action combination for pre- and post-NF measures.

The 2 × 2 ANOVA with Emotion (Angry and Happy) and Action (Pull and Push) showed no significant main effect of Emotion ($F(1,44) = 10.2, p = .0102, \eta^2_p = 0.19$) but a significant main effect of Action ($F(1,44) = 5.92, p = .019, \eta^2_p = 0.12$), and a significant interaction between them ($F(1,44) = 6.67, p = .013, \eta^2_p = 0.13$). Tests of simple main effects showed that RT means were not significantly different between Happy-Push and Happy-Pull trials ($F(1,44) = 1.4, p = .243, \eta^2_p = 0.03$) but were significantly faster for Angry-Push than Angry-Pull trials ($F(1,44) = 10.93, p = .002, \eta^2_p = 0.20$). Moreover, RT means were faster for Happy-Pull than Angry-Pull trials ($F(1,44) = 6.18, p = .017, \eta^2_p = 0.12$), and also significantly faster for Angry-Push than Happy-Push trials ($F(1,44) =$...
4.45, \( p = .039, \eta^2_p = 0.09 \).

Angry effect scores were not significantly associated with social anxiety \( r(45) = -0.07, p = .669 \), but happy effect scores negatively correlated with symptoms \( r(45) = -0.33, p = .029 \) such that individuals with higher social anxiety avoided happy faces more.

2.2. Correlations between social anxiety and socially-avoidant behaviours, and initial FC

There was a non-significant negative correlation between initial FC and AAT happy effect scores \( r(40) = -0.30, p = .064 \), but a significant positive correlation between initial FC and AAT angry effect scores emerged \( r(40) = 0.32, p = .047 \), suggesting that initial FC is more positive in individuals who approach angry faces more. The correlation between SAS-A score and initial FC was not significant \( r(40) = 0.19, p = .246 \). These results held true for the smaller sample that received NF training. Age (in months) and initial FC were not significantly correlated \( r(40) = -1.12, p = .46 \).

2.3. Pre-to-post NF changes in socially-avoidant behaviour depending on neurofeedback training ability

The 2 \( \times \) 2 \( \times \) 2 mixed ANOVA, with age as a covariate, showed a significant 3-way interaction between time, emotion and training direction group \( F(1,23) = 8.83, p = .007, \eta^2_p = 0.28 \). The 2 \( \times \) 2 mixed ANOVA showed a significant 3-way interaction between time, emotion and training direction group \( F(1,23) = 8.83, p = .007, \eta^2_p = 0.28 \). To decompose this interaction a Time-by-Emotion ANOVA was conducted for each group. For the maladaptive group, neither the main effects of Time or Emotion were significant, however the Time-by-Emotion interaction was significant \( F(1,12) = 5.84, p = .034, \eta^2_p = 0.35 \). To explore this two-way interaction, we assessed the main effect of time for each emotion in the maladaptive group: Happy effect scores significantly decreased from pre \( (M = 49.46, SD = 70.87) \) to post \( (M = 3.04, SD = 106.62) \) NF training \( F(1,11) = 5.78, p = .035, \eta^2_p = 0.34 \), suggesting that avoidance of happy faces increased. Of note, decomposing the Happy effect scores into raw scores for Happy push and Happy pull (Supplementary Table 1) showed that this change was driven by reduced reaction times in pushing away Happy faces \( t(12) = 3.51, p = .004 \) with no significant change in pulling Happy faces towards \( t(12) = 0.99, p = .340 \). Angry effect scores were not significantly different pre \( (M = -54.96, SD = 64.28) \) to post \( (M = -20.69, SD = 107.13) \) NF training \( F(1,11) = 0.57, p = .47, \eta^2_p = 0.05 \). For the adaptive direction group, there were no main effects of Time \( F(1,11) = 0.02, p = .88, \eta^2_p = 0.00 \), Emotion \( F(1,11) = 0.25, p = .63, \eta^2_p = 0.02 \) or an interaction effect, \( F(1,11) = 0.73, p = .41, \eta^2_p = 0.06 \).

2.4. Pre-to-post NF changes in self-report positive reappraisal depending on neurofeedback training ability

There was a main effect of Time \( F(1,24) = 4.76, p = .01, \eta^2_p = 0.24 \). Although there was no significant interaction with Training direction \( F(1,24) = 2.29, p = .14, \eta^2_p = 0.09 \), due to a priori expectations around changes in reappraisal, we nonetheless carried out separate paired sample t-tests for each group on the pre and post-NF variables. The reduction in positive appraisal from pre \( (M = 6.50, SD = 2.10) \) to post \( (M = 5.71, SD = 2.37) \) in the maladaptive group was significant after correction for multiple comparisons \( t(13) = 2.80, p < .015, d = 0.53 \) but not amongst the adaptive group \( (pre: M = 6.92, SD = 2.10; \text{post: } M = 6.70, SD = 1.97; t(12) = 0.61, p = .553, d = 0.24) \).

3. Discussion

The current study tested whether real-time fMRI neurofeedback (NF) could target neural correlates of emotion regulation (ER) and alter socially-avoidant behaviour in unselected adolescents. We assessed whether any improvement in cognitive reappraisal abilities, targeted through NF of functional connectivity between the DLPFC and amygdala, would also be observed. Amongst individuals unable to acquire an adaptive pattern of connectivity (an increasingly negative connectivity between the DLPFC and amygdala) through NF training, there was an increasing tendency to avoid happy faces from pre to post-NF training. These same participants showed a significant decrease in self-report positive reappraisal ability following NF training. These changes were absent in the group able to acquire an adaptive pattern of connectivity. As expected, all individuals pulled happy faces faster than angry faces and pushed angry faces faster than happy faces, but social approach-avoidance tendencies differed amongst individuals with social anxiety: Those with higher social anxiety showed greater avoidance of happy faces than those with lower levels. Initial positive functional connectivity between the amygdala and DLPFC was associated with the tendency to approach angry faces (but not with social anxiety).

The findings show that among individuals who did not respond to NF training, socially avoidant behaviour (of happy faces becomes more pronounced with a more exaggerated reduction in reappraisal ability (relative to baseline). These results fall in line with studies showing that an absence of the “adaptive” connectivity is correlated with social anxiety in adults (Kim et al., 2011). They also illustrate a potentially aversive consequence of failing to engage with the NF technique. Whilst our results did not show improvement of avoidant behaviour in the “adaptive” group, they do demonstrate the absence of deteriorations. It may be the case that with further development of this relatively exploratory training technique, possibly administered over multiple sessions to identify and consolidate effective strategies, we could see positive changes in cognitive reappraisal, reductions in withdrawal behaviour and increases in approach behaviour amongst the ‘adaptive’ group. However, for the ‘maladaptive’ group, multiple sessions could exaggerate the aversive effect associated with an inability to acquire training. This suggests future research should first focus on the salient factors differentiating responders and non-responders in order to ensure training approaches can be adapted appropriately.

Perhaps due to the non-clinical nature of the sample, social anxiety correlated not with avoidance of angry faces (Roelofs et al., 2010) but happy faces. Evolutionary-based avoidance tendency for angry faces may exist in all individuals regardless of anxiety (Marsh et al., 2005), however, due to the nature of social anxiety - where individuals are excessively concerned about negative social evaluation - differences in avoidant behaviour may only become apparent to happy faces, due to the distinct lack of threat interpretation to these stimuli by healthy compared with anxious individuals. Previous studies have reported that anxious individuals avoid happy faces, at automatic and controlled levels of processing (Heuer et al., 2007; Mansell, Clark, Ehrlers, & Chen, 1999). Finally, when investigating how initial connectivity may impact...
existing approach-avoidance behaviours, we found a greater likelihood to approach angry faces in those individuals with a ‘maladaptive’ pattern of connectivity between DLPFC and amygdala. This unexpected finding may signal a maladaptive tendency that could be linked to other behavioural problems such as aggression, though without these measures, we were unable to assess this.

There are some study limitations. Firstly, although we measured reappraisal before and after NF training, we did not know whether participants were deploying reappraisal ability during NF training. Moreover, our measure of reappraisal was based on only two items from the CERQ, a measure that typically measures emotion regulation strategies as traits and may therefore be less amenable to change following a single training session. Future research should measure state aspects of reappraisal to give a more accurate picture over whether changes in cognitive reappraisal ability were targeted during NF training, and mediated changes in social avoidance. Second, the modest sample size in each group may have limited the significance of some statistical comparisons. We also used an all-female sample. This was to limit homogeneity in the sample given many age and gender effects in adolescence but restricts generalizability of the findings to all adolescents. Similarly, data from unselected adolescents cannot inform whether the same findings characterise clinically-anxious patients. Finally, the degree to which AAT reflects real-life behavioural avoidance of social situations is questionable.

4. Conclusions

This study demonstrated that in our non-clinical sample of female adolescents, socially avoidant behaviour of positive faces was associated with greater social anxiety. When using neurofeedback training to alter cognitive reappraisal, we found that those who were unable to acquire a more adaptive pattern of connectivity showed increased avoidance of happy faces and decrease in positive appraisal ability. These results suggest that NF training can have a differential effect on cognitive reappraisal ability and subsequent social approach-avoidance tendencies, however, at present this effect is not in the desired direction. Further research is required to understand factors differentiating individuals who show difficulties responding to training from those who do respond. Using our initial findings on the proportion of young people who do and do not respond to training and the effect sizes of within-group changes in social avoidance in each group, future studies can conduct larger and powered studies to identify the optimal parameters for positive outcomes.
