A Single-Component Luminescent Biosensor for the SARS-CoV-2 Spike Protein

Matthew Ravalin, Δ Heegwang Roh, Δ Rahul Suryawanshi, G. Renuka Kumar, John E. Pak, Melanie Ott, and Alice Y. Ting*

ABSTRACT: Many existing protein detection strategies depend on highly functionalized antibody reagents. A simpler and easier to produce class of detection reagent is highly desirable. We designed a single-component, recombinant, luminescent biosensor that can be expressed in laboratory strains of Escherichia coli and Saccharomyces cerevisiae. This biosensor is deployed in multiple homogeneous and immobilized assay formats to detect recombinant SARS-CoV-2 spike antigen and cultured virus. The chemiluminescent signal generated facilitates detection by an unaugmented cell phone camera. Binding-activated tandem split-enzyme (BAT) biosensors may serve as a useful template for diagnostics and reagents that detect SARS-CoV-2 antigens and other proteins of interest.

INTRODUCTION

The detection and quantification of analytes in complex biological samples is essential for both discovery and translational biomedical research. Small-molecule and protein analyte detection are dominated by antibody-based technologies. Such technologies have three major limitations: (1) antibodies are generally produced in mammalian expression systems that require significant infrastructure, (2) nearly all antibody-based assays require chemical modification to immobilize the antibodies or conjugate detection reagents, and (3) these platforms require at least two and up to four unique antibodies to function. To address these limitations, we and others have developed alternative biosensor platforms that can be more easily produced and work in both homogeneous and immobilized assay formats. 1

Split luciferase enzymes are attractive for biosensor design because they are highly sensitive and, in contrast to fluorescent reporters that require an excitation source, need only a camera for detection. Several two-component luciferase-based biosensors have been reported, in which analyte binding drives the reconstitution of the split enzyme (Figure S1a,b). 2−8 A challenge with such sensors is the requirement for two separate binding modules that interact with independent epitopes on the target analyte. Recently, the LOCKR platform used a binding module grafted into a caging structure that allows for enzyme reconstitution triggered by analyte binding (Figure S1c). 9−11 In this system, the binding module serves as the “lock” for a caging structure that masks one half of the split luciferase. The analyte serves as a “key” that opens the cage and allows the association of the other half of the split luciferase, which is added as a second component.

Single-component luminescent biosensors are potentially simpler to produce and easier to use. Existing designs rely on naturally occurring binding modules that undergo large conformational changes upon analyte binding (Figure S1d), tethered decoy analytes that stabilize an autoinhibited state of the sensor (Figure S1e), or bioluminescence resonance energy transfer (BRET). 12−16 These approaches are difficult to generalize and limit the scope of analytes that can be detected. Here we introduce a single-component, NanoLuc-based, binding-activated tandem split-enzyme (BAT) biosensor. BATs bypass the need for a large conformational change in the binding module or competition with a tethered decoy in other single-component platforms. We employ this luminescent BAT biosensor for the detection of the SARS-CoV-2 spike protein in multiple assay formats.

RESULTS

Design and Optimization of SARS-CoV-2 Biosensor “S-BAT”. In our design, a small, rigid binding module is fused to split luciferase halves in such a fashion as to disfavor their reconstitution, due to unfavorable geometry and low effective

concentration. Antigen binding introduces steric clashes with the luciferase halves that reorient them and increase their effective concentration, driving reconstitution (Figure 1a, Figure S1f). To demonstrate the BAT concept, we selected the computationally designed miniprotein LCB1 as our binder. LCB1 binds to the receptor binding domain (RBD) of SARS-CoV-2 spike protein with a $K_d$ of $10^{-10}$ M.

In addition to having high thermal stability, rigidity, and no disulfide bonds to complicate purification, the N- and C-termini in the three-helix bundle scaffold project in opposite directions (≈25 Å apart, based on measurements from PDB ID7JZU), providing a rigid scaffold for minimizing the effective concentration of the fused split luciferase halves. We selected the split luciferase NanoBiT for BATs. NanoBiT is based on the bright, blue-emitting, ATP-independent, cysteine-free luciferase NanoLuc, and its SmBiT and LgBiT components have relatively low affinity for one another ($K_d$ ≈ 190 μM).

In a previous study, the tandem fusion FKBP12-SmBiT-Linker-LgBiT-FRB showed minimal background reconstitution in the absence of rapamycin. We performed a linker screen, varying the glycine-serine-rich sequence between LCB1 and NanoBiT fragments between 0 and 15 amino acids (Figure 1b). The initial library consisted of 16 constructs (LCB1 Linker1 length, Linker2 length), which were expressed in E. coli fused to a TEV protease-cleavable N-terminal His$_6$ tag. TEV cleaved constructs were screened in a NanoGlo assay (Promega) for their ability to detect 1 nM (146.7 ng/mL) recombinant spike derived from the WA1 strain of SARS-CoV-2 in a homogeneous microplate assay. The data from this screen clearly indicated that the absolute change in the signal ($S - N$) and the signal-to-noise ratio ($S/N$) increased as the linker length decreased, with LCB10−0 yielding the best composite performance ($S/N \times (S - N)$). Based on apparent instability of LCB10−0 and the dramatic increase in $S/N$ between 5 and 0 linker 1 lengths, we further optimized linker 1

Figure 1. Design of a binding-activated tandem split-enzyme (BAT) biosensor for the SARS-CoV-2 spike protein. (a) BATs consist of a binding module (B, gray) for antigen (red) and a split enzyme (1 and 2, blue). The split enzyme is fused in tandem to the N- and C-termini of the binding module. A low effective concentration of 1 and 2 in the “OFF” state limits background activity. Binding-induced steric clashes between the antigen and the tethered split enzyme components increase the effective concentration of 1 and 2, driving reconstitution in the “ON” state. (b) Model of an activated BAT (left) composed of SmBiT (light blue, cartoon), the miniprotein LCB1 (gray, cartoon), and LgBiT (blue cartoon) bound to the receptor binding domain (RBD, red, surface) of the SARS-CoV-2 spike protein. The lengths of linker 1 and linker 2 (right, black, dashed) are likely to control the effective concentration of SmBiT and LgBiT in the absence of the binder. (c) Heat map of BAT performance as a function of linker length. Performance (signal-to-noise ratio ($S/N$) multiplied by the magnitude of signal change ($S - N$)) for each linker composition is plotted based on the detection of 1 nM recombinant spike in phosphate-buffered saline (PBS). The best linker combination was a single amino acid (Gly) for linker 1 and 0 length linker for linker 2. This molecule is named S-BAT. (d) Asp 30 in LCB1 (gray, cartoon) makes critical contacts with Arg 403 and Lys 417 in the RBD of the SARS-CoV-2 spike protein (red, cartoon). Mutation of Asp 30 to Ala yields S-BAT*, which is not activated by recombinant spike (middle panel) or RBD (right panel). Luminescence is plotted in arbitrary units (AU) versus antigen concentration (molar, M) for individual replicate samples ($n = 3$) in a representative experiment.
S-BAT Is Functional in Multiple Assay Formats. While homogeneous assays are convenient in a laboratory setting, immobilized assay formats can offer versatility in a variety of use settings. Previous work has shown that BRET-based biosensors can detect analytes of interest following adsorption onto cellulose paper, relying on a ratiometric output of luminescence and fluorescence for the detection of analytes.\textsuperscript{19} We adsorbed our S-BAT sensor onto paper and used the change in luminescence intensity as our signal. With this approach, we were able to specifically detect low nanomolar concentrations of antigen using S-BAT, with S-BAT\textsuperscript{*} serving as a negative control (Figure 2a). Adsorption-based immobilization is advantageous in that it requires no chemical modification to the protein reagent. However, chemical conjugation with biotin and subsequent immobilization on streptavidin allow for the concentration of the biosensor on the surface of a heterogeneous assay matrix and can minimize loss of signal intensity inherent in the use of an opaque porous matrix such as cellulose paper. Due to the absence of disulfide bonds in our constructs (in contrast to antibodies), we could introduce single cysteine residues throughout the protein as a handle for site-specific bioconjugation. We generated five constructs containing a single cysteine residue and conjugated biotin-PEG\textsubscript{n}-maleimide (where n = 2 or 11) to each.

The lateral flow assay (LFA) is a workhorse platform for the rapid detection of biomolecules in clinical and laboratory settings.\textsuperscript{20} To demonstrate that BATs are amenable to use in the LFA format, we screened our library of 10 conjugates (5 sites × 2 linker lengths) against 10 nM (1466.7 ng/mL) recombinant spike. The sample (antigen or buffer), biotinylated sensor, and NanoGlo reagent were incubated in solution for 10 min. After incubation, a streptavidin-functionalized LFA strip was immersed in the sample and allowed to incubate for an additional 10 min. The LFA strips were removed and imaged on a Bio-Rad ChemiDoc gel imaging system equipped with a CCD camera. The screen data demonstrated that the PEG\textsubscript{11} constructs tended to yield higher signal in this format and that while conjugation at position 66 yielded the highest signal, immobilization via the N-terminus (position 16, PI’ of the TEV cleavage site) gave the lowest background (Figure S3a,b). In this format S-BAT (Cys16-PEG\textsubscript{11}-biotin) was able to detect 1 nM (146.7 ng/mL) recombinant spike (Figure 2b).

The ELISA is a staple of clinical and laboratory testing. However, ELISAs require multiple functionalized antibody reagents and multiple rounds of washing and development steps. We envisioned using immobilized BATs to create an assay with the same form factor but that required no washing and fewer reagents. To this end, we immobilized S-BAT (Cys16-PEG\textsubscript{11}-biotin) on a white 96-well plate precoated with streptavidin. Addition of sample and substrate to the well was sufficient to enable detection of low nanomolar concentrations.

Figure 2. Application of S-BAT to immobilized assay formats. (a) S-BAT or S-BAT\textsuperscript{*} was adsorbed onto cellulose paper and dried in a vacuum desiccator. Spotting of antigen and substrate on the paper yielded detectable signal upon imaging with a CCD camera. The bright field (BF, top) and chemiluminescent (bottom) images for a serial dilution of recombinant spike are shown. (b) S-BAT (Cys16-PEG\textsubscript{11}-biotin) was mixed with a serial dilution of recombinant spike and substrate and then resolved on a lateral flow assay (LFA) strip functionalized with streptavidin. The bright field (BF, left) and chemiluminescent (right) images demonstrate detection at 1 nM recombinant spike concentration. (c) Streptavidin-functionalized agarose beads were functionalized with S-BAT (CysX-PEG\textsubscript{11}-biotin) constructs and incubated with either buffer or 10 nM recombinant spike. After addition of substrate, the beads were settled by centrifugation and imaged with a CCD camera. Biotinylation at Cys16 gave the best signal-to-noise ratio.
of recombinant spike by imaging without any washing steps in 10 min (Figure S3c). The LFA and plate assays are versatile assay formats; however, both are limited in the volume of sample that they can accommodate. To circumvent this limitation, we developed a bead-based reagent that could be incubated with a larger sample volume, isolated by centrifugation or filtration, and would concentrate signal incubated with a larger sample volume, isolated by centrifugation or filtration. These results were consistent with our library of biotinylated S-BAT constructs immobilized on streptavidin-functionalized agarose beads against 10 nM (1466.7 ng/mL) recombinant spike in reactions where the bead volume was 5% of the total volume. The beads were settled by centrifugation and analyzed by imaging the tube with a CCD camera. These results were consistent with our previous screen in the LFA format in that PEG11 linkers yielded the highest signal and conjugation at Cys16 yielded the highest signal-to-noise ratio (Figure 2c). BATs appear to be a flexible platform for protein analyte detection in multiple assay formats.

**BATs Accommodate Purification-Free Detection of Antigen.** While the production of protein reagents such as S-BAT in bacteria is simple and low-cost relative to the production of antibody reagents, it still requires significant protein purification infrastructure to achieve. We wanted to develop a protocol for the production and use of S-BAT that did not require purification. In a first iteration we simply expressed S-BAT and S-BAT* in the cytoplasm of BL21(DE3) *E. coli* with no affinity purification tag. A chemical lysis step followed by centrifugation and filtration yielded the clarified lysate as the working reagent. Dilution of the lysate and addition of antigen demonstrated that the crude lysate could detect recombinant spike with sensitivity and specificity on par with the purified protein reagent (Figure 3a). Despite the low input necessary to culture *E. coli* at scale, certain aspects of their cultivation make them a suboptimal expression host for protein expression at scale, certain aspects of their cultivation make them a suboptimal expression host for protein expression system that did not require the chemical lysis was desirable. To this end we produced strains of *S. cerevisiae* that secreted S-BAT and S-BAT* into their growth media. We found that filtered culture media from these yeasts were able to yield sufficient signal to detect 1 nM (146.7 ng/mL) recombinant spike after 24 h of induction of S-BAT expression (Figure 3b). Moreover, S-BAT can detect antigen as a component of complex mixtures. When RBD is diluted in neat fetal bovine serum (FBS), S-BAT performance is maintained (Figure S4). These experiments demonstrate that S-BAT is robust in that it can function as a component of complex mixtures. In instances where the production of purified antigen is a challenge, such as with transmembrane protein targets, detection via BATs in intact mammalian cells could be desirable. To illustrate this, we expressed full-length SARS-CoV-2 spike protein, which contains a single-pass transmembrane anchor at its C-terminus, in HEK-293T cells. After 24 h of expression, we incubated cells with either 10 nM S-BAT or S-BAT* for 1 h in complete cell culture media. The cells were washed and incubated with live cell Nano-Glo reagent in complete cell culture media. The cells were imaged with...
a CCD camera. These experiments demonstrated that signal was dependent on the expression of spike and the integrity of LCB1 binding (Figure 3c). In total these experiments show that BATs can facilitate the detection of antigen in crude formats.

**Detection of Cultured SARS-CoV-2 Virus.** As the SARS-CoV-2 pandemic has continued, the emergence and characterization of dominant variants has been a significant focus of research efforts. With time and transmission, the sequence composition of the spike protein and in particular the RBD have changed. LCB1 was originally designed to competitively antagonize the interaction between ACE2 and the RBD domain of the spike protein, the critical protein−protein interaction required for cell entry. Since this interface is critical to viral entry and propagation, it might be expected that mutation to the interface would in general be deleterious to the virus. However, as the determinants of binding for ACE2 and LCB1 to RBD are overlapping but not identical, the probability that mutations could arise that differentially affect native receptor versus LCB1 binding is significant. We tested a panel of purified RBDs derived from sequences of prominent variants that have arisen throughout the pandemic (WA1, B1.1.7, B1.351, P1, B1.617.1 and B1.617.2). Given that B1.351 and P1 variants have a mutation at K417, which forms the key salt bridge with D30 in LCB1, we anticipated that these variants would completely evade detection by S-BAT. B1.1.7 contains an N501Y mutation in the RBD, which also has a high probability of disrupting S-BAT recognition (Figure 4a).

Indeed, when screened against 100, 10, and 1 nM of each recombinant RBD, we were unable to detect B1.351 and P1 variants, while B1.1.7 showed an attenuated signal. Both B1.617.1 and B1.617.2 were readily detected at this concentration. Therefore, S-BAT successfully detected both WA1 and Delta variants of SARS-CoV-2. Mature virus particles diluted serially in media (grayscale bars) were compared to 1 nM recombinant spike (red, bar) and media (blue, bar). Virus was titered and standardized by a plaque assay and diluted based on plaque-forming units (PFU). Luminescence is plotted in arbitrary units (AU) for individual replicate samples (n = 3) in a representative experiment.

**Figure 4.** Detection of cultured SARS-CoV-2 variants with S-BAT. (a) Positions of receptor binding domain (RBD, red, cartoon) mutations (yellow, sphere) in variants of concern relative to the LCB1 (gray, cartoon) binding site. (b) Screening of recombinant RBDs at 100, 10, and 1 nM from variants of concern WA1, P1 (Gamma), B1.1.7 (Alpha), B1.351 (Beta), P1.617.1 (Kappa), and P1.617.2 (Delta) predicted that WA1, Kappa, and Delta would be robustly detected by S-BAT. SARS-CoV-2 nucleocapsid protein (N-Protein) yielded no signal in the assay. (c) S-BAT detection of live cultured virus demonstrates the predictive power of the recombinant antigen screen. S-BAT successfully detected both WA1 and Delta variants of SARS-CoV-2. Journal of the American Chemical Society
concentration, consistent with the fact that they each carry RBD mutations distal to the ACE2/LCB1 binding site (Figure 4b, Figure S5a).

To understand the correlation between our in vitro RBD assay and our ability to detect cultured, live SARS-CoV-2 virus, we selected WA1 and B1.617.2 (Delta) as probable positive variants and B1.351 (Beta) as a probable negative variant. Virus was screened at concentrations consistent with clinical isolates from nasopharyngeal swabs.

As predicted by the results with recombinant RBD, we were able to detect cultured virus from WA1 (the first strain detected in the United States) and B1.617.2 (Delta variant) and unable to detect cultured virus from B1.351 (Beta variant) (Figure 4c, Figure S5b). S-BAT* signal did not change when incubated with any cultured virus variant (Figure S5b,c,d). The predictive value of the recombinant antigen assay for cultured virus detection lowers the activation barrier for testing and adapting this and any future generations of S-BAT against variants of concern as they emerge.

Figure 5. Detection of SARS-CoV-2 spike protein using S-BAT and a cell phone. (a) Computer-aided design (CAD) model of the cell phone case (left) and cover (right) for low-light imaging of chemiluminescence. (b) Reactions were set up in a disposable microcuvette with a cap (left panel), placed into the iPhone SE cell phone case 3D printed in ABS thermoplastic (center panel), and capped to exclude ambient light (right panel). (c) Reactions were set up in 400 μL with 180 μL sample, 20 μL of 200 nM S-BAT or S-BAT*, and 200 μL of 2× substrate, incubated for 10 min, and a RAW image was taken using the HALIDE photography application. Since the signal in the image was not homogeneous, a grid search of a prototype image was used to identify a region of interest (ROI) with the highest signal intensity using the RAW image analysis software RAWDigger. (d) Use of the optimized ROI (bottom histogram) rather than the entire image (top histogram) yielded better separation between a high-signal sample (100 nM recombinant spike, black) and the negative control (PBS, white). Data are plotted as pixel intensity × pixel count such that the area under the histogram represents the total blue intensity for the analyzed region. (e) Plots of average blue intensity for the ROI of S-BAT incubated with recombinant spike (open circle, left panel) or S-BAT* incubated with recombinant spike (filled circle, left panel). The same plot for S-BAT incubated with recombinant spike (open circle, right panel) or S-BAT incubated with bovine serum albumin (BSA) (filled circle, right panel). Replicates are three images taken of the same sample in sequence. Solid lines are a linear regression of each data set. Dashed lines are ±3σ of the negative control (PBS). Average intensity is plotted in arbitrary units (AU) versus antigen concentration (nM) for technical replicates (n = 3) in a representative experiment.
are sufficiently eliminating ambient light and maximizing photon collection from the sample. To achieve this, we designed and fabricated an adaptor to an iPhone SE (2020) with the form factor of a cell phone case (Figure 5a). The case was designed to accommodate a homogeneous sample placed in a disposable microwell (Figure 5b). The case itself was fabricated on a 3D printer from black ABS thermoplastic based on its high opacity. The inside of the reaction chamber was covered with a diffuse reflective coating to minimize the loss of emitted photons. The cuvette was positioned as close as possible to the camera aperture. RAW images were acquired, and a region of interest (ROI) was selected based on where in the image the blue light intensity was highest. The use of an optimized ROI rather than the entire image enhanced the dynamic range of the measurement (Figure 5c, Figure S6). To define a limit of detection (LOD) for the cell phone acquisition, we incubated decreasing amounts of WA1 recombinant spike with 10 nM S-BAT and compared the mean intensity to vehicle (phosphate-buffered saline (PBS) buffer). S-BAT incubated with recombinate spike and S-BAT incubated with bovine serum albumin (BSA) yielded no detectable increases in signal (Figure 5d,e). Using a cutoff of 3σ we were able to detect a lower limit of 300 pM (44.0 ng/mL) recombinant spike with this detection method. This sensitivity is on par with the reported molar LOD for small-molecule luciferin substrate it uses, furimazine, is expensive, unstable, and proprietary. Adapting BATs to incorporate a different reporter enzyme system such as peroxidases, alkaline phosphatase, or other nonproprietary luciferase enzymes may yield systems that can incorporate more robust and accessible substrate classes with the capacity to yield both luminescent and colorimetric readouts. Future work will focus on adapting BATs to other antigens and further exploring the modularity of this platform.

■ MATERIALS AND METHODS

**Cloning.** All BAT constructs were ordered from Twist Biosciences (see DNA and protein sequences in the Supporting Information) and were subcloned into a pET backbone (https://www.addgene.org/296598/) using NcoI and BamHI restriction sites via a Gibson assembly. For yeast secretion constructs, sequences for S-BAT and S-BAT* were subcloned into the pcTCCON2 backbone (https://www.addgene.org/73152/) using the EcoRI and XhoI restriction sites via a Gibson assembly.

**Recombinant Protein Production.** Plasmids encoding BAT sensors were transform to *E. coli* BL21 (DE3) competent cells (Agilent). Transformants from a single colony were used to inoculate 5 mL of LB supplemented with 100 μg/L kanamycin (LB-Kan) and grown overnight at 37 °C, 220 rpm. The overnight seed culture was diluted 1:100 LB-Kan medium and was incubated at 37 °C, 220 rpm, until the OD_{600} was between 0.4 and 0.6. The cells were then induced by adding IPTG to a final concentration of 1 mM and grown for another 20 h at room temperature. After induction, cells were harvested by centrifugation at 10000g for 20 min. The cell pellet was resuspended in 1:4 w/v (g/mL) B-PER reagent (Thermo Fischer) supplemented with PMSF and protease inhibitor cocktail and incubated for 15 min at room temperature. The cellular debris was removed with centrifugation (21300g, 30 min, 4 °C), and the supernatant was cleared using a syringe filter (0.45 μm, PVDF, Millipore). The filtered lysate was batch loaded to 0.5 mL of packed Ni-Nta resin. The column was washed two times with 5 mL of wash buffer (50 mM Tris-HCl pH 8.0, 300 mM NaCl, 30 mM imidazole). The protein was then eluted using a total of 4 mL of elution buffer (50 mM Tris-HCl pH 8.0, 300 mM NaCl, 200 mM imidazole). The fractions were analyzed using SDS-PAGE, and the fractions containing the uncleaved BAT sensor were collected. The uncleaved BAT sensors were concentrated to ~1.0 mL, and the concentration was calculated from the A280 value. The His tag at the N-terminus was cleaved by adding the His-tagged TEV protease at 1:50 molar ratio to the protein. The mixture was dialyzed into TEV reaction buffer (20 mM Tris-HCl pH 8.0, 150 mM NaCl, 0.5 mM TCEP-HCl) overnight at 4 °C. The mixture was loaded to Ni-Nta resin, and the cleaved BAT sensor was collected by keeping the flow-through. The cleaved BAT sensor was analyzed into PBS pH 7.4 overnight at a 4 °C. The purity of the cleaved sensor was analyzed using SDS-PAGE, and the final product was stored 4 °C for further use. S-BAT and S-BAT* were further purified by size exclusion chromatography on a HiLoad 16/600 Superdex 75 75 column run on an Akta go protein purification system (Cytiva) in PBS. Typical yields for S-BAT were 8 mg/L of bacterial culture. This is sufficient material to carry out ~60 000 assays in a 384-well format. Material is stable for >6 months stored at 4 °C in PBS. S-BAT variants containing single cysteine residues were purified by the same protocol but dialyzed into 20 mM HEPES pH 7.4, 150 mM NaCl, and 1 mM (tris(2-carboxyethyl)phosphine) (TCEP). Biotin conjugates were prepared by the addition of 2 equiv of maleimide-PEG-biotin or maleimide-PEG-biotin overnight at 4 °C. Excess biotinyl conjugate was removed by iterative dilution and concentration in PBS pH 7.4. Tag-free S-BAT produced in *E. coli* was expressed and extracted as above on a 5 mL scale. After chemical lysis, the crude mixture was filtered through a 0.45 μm PVDF syringe filter. The filtrate was diluted 1:100 in PBS pH 7.4 prior to use.

The pcTCCON2 plasmids encoding the secreted BAT sensors were transformed into *S. cerevisiae* strain EBY100 using Frozen-EZ yeast transformation kit II (Zymo Research). Transformants from a single colony on Trp-deficient SDCAA plates were grown and used for
subsequent yeast experiments. Trp-deficient SDCAA and SGCAA media were used, for propagating and inducing yeast cells harboring the S-BAT sensor secretion plasmid, respectively. Yeast cells were induced by inoculating 1.8 mL of SGCAA medium with 0.2 mL of saturated yeast culture (OD600 = 15) maintained in SDCAA medium. After inducing for 24 h at 30 °C, 250 rpm, the cells were pelleted by centrifugation at 3000g for 2 min. The supernatant was cleared using a syringe filter and used for subsequent detection assay.

Plasmids encoding SARS-CoV-2 spike (S) ectodomain or receptor binding domain were transiently transfected into suspension Exp293 cells at 1–1.5 L scale in 2.8 L of optimum growth flasks (Thomson Scientific), following the manufacturer’s guidelines. Three days after transfection, cell cultures at 75% viability were centrifuged at 500g for 30 min, followed by filtration of the supernatant using a 0.45 μm Nalgene Rapid Flow filter unit. The supernatant was adjusted to pH 7.4 and directly loaded onto a 5 mL HisTrap Excel column pre-equilibrated with 20 mM sodium phosphate and 500 mM NaCl, pH 7.4, using an AKTA Pure. Captured proteins were washed with 60 column volumes (CVs) of (20 mM sodium phosphate, 500 mM NaCl, 20 mM imidazole, pH 7.4) and eluted with 10 CVs of (20 mM sodium phosphate, 500 mM NaCl, 500 mM imidazole, pH 7.4). Eluted proteins were buffer exchanged into PBS using either three kDa MWC0 (for RB) or 100 kDa MWC0 (for spike) Amicon concentrators, supplemented with 10% glycerol, and filtered prior to storage at −80 °C.

RBDS from SARS-CoV2 variants of concern and N-protein were purchased from Sino Biological and reconstituted from lyophilized powder as per the manufacturer’s instructions.

**Homogenous Detection of Recombinant Spike or RBDD.** All BAT sensors were diluted into PBS pH 7.4 to the final concentration of 4 nM prior to the spike detection assay. The final concentration of sensor in these assays was 1 nM. The stock of recombinant spike was diluted into PBS pH 7.4. A 20 μL amount of diluted sensor was mixed with 20 μL of diluted recombinant spike in a PCR tube, mixed well by pipetting, and incubated for 1 h at room temperature. A 25 μL amount of this mixture was mixed with 25 μL of Nano-Glo luciferase assay reagent (Promega), following the manufacturer’s protocol, in a 96-well plate, incubated overnight, and infected with a range of virus dilutions (10−6–10−3) for 1 h prior to overlay by 2.5% Avicel (Dupont, RC-591). After 72 h, the Avicel was removed, and cells were fixed in 10% formalin for 1 h and stained with crystal violet for 10 min to visualize plaque-forming units.

For S-BAT detection experiments, 25 μL of virus dilutions were combined with 25 μL of spike sensor (diluted in PBS from 4x stock) in 96-well white polystyrene microplates (Corning). Luminance was measured via plate assays on Vero-E6 cells. Briefly, 0.2 × 106 cells per well were seeded in 12-well plates, incubated overnight, and infected with a range of virus dilutions (10−6–10−3) for 1 h prior to overlay by 2.5% Avicel (Dupont, RC-591). After 72 h, the Avicel was removed, and cells were fixed in 10% formalin for 1 h and stained with crystal violet for 10 min to visualize plaque-forming units.

**Cell Phone Detection.** The cell phone adaptor was designed to fit an iPhone SE (2020) and accommodate a disposable semi-transparent filament. A total of 7.5 × 106 cells were plated and grown overnight in complete Dulbecco’s modified Eagle medium (DMEM) (10% FBS, 1% penicillin/streptomycin). The following day the cells were transfected with 500 ng of plasmid DNA encoding the full-length WA1 SARS-CoV-2 spike protein behind a CMV promoter using polyethylenimine. After 5 h the media was changed, and cells were grown for an additional 20 h. S-BAT and S-BAT* were diluted to 10 nM in complete media and incubated with cells for 1 h. Media was removed, and cells were washed 3× with complete media. Live cell NanoGlo (Promega) was diluted in complete media, and 1 mL was added to the cells. Cells were imaged on a ChemiDoc XR (BioRad) imaging system with a 10 s exposure time.

**SARS-CoV-2 Virus Culture and Detection.** All SARS-CoV-2 live virus experiments were performed in a biosafety level 3 facility with approved procedures at the Gladstone Institutes. SARS-CoV-2 isolates and variants USA-WA1/2020, B.1.351 (Beta), and B.1.617.2 (Delta) were procured from BEI Resources. The virus was cultured in Vero-E6 cells (obtained from ATCC and grown in DMEM (Corning) supplemented with 10% FBS (GeminiBio), 1% glutamine (Corning), and 1% penicillin/streptomycin (Corning) at 37 °C, 5% CO2). Stocks were stored at −80 °C. Virus titer was determined via plaque assays on Vero-E6 cells. Briefly, 0.2 × 106 cells per well were seeded in 12-well plates, incubated overnight, and infected with a range of virus dilutions (10−6–10−5) for 1 h prior to overlay by 2.5% Avicel (Dupont, RC-591). After 72 h, the Avicel was removed, and cells were fixed in 10% formalin for 1 h and stained with crystal violet for 10 min to visualize plaque-forming units.

For S-BAT detection experiments, 25 μL of virus dilutions were combined with 25 μL of spike sensor (diluted in PBS from 4x stock) in 96-well white polystyrene microplates (Corning) and incubated for 1 h at room temperature. Next, 50 μL of 2x Nano-Glo buffer was added and mixed by gentle pipetting, the plate was sealed and incubated at room temperature for 10 min, and luminence was measured (Promega GloMax luminometer). Recombinant spike and media served as positive and negative controls, respectively.

**Cell Phone Detection.** The cell phone adaptor was designed to fit an iPhone SE (2020) and accommodate a disposable semi-transparent filament. A total of 7.5 × 106 cells were plated and grown overnight in complete Dulbecco’s modified Eagle medium (DMEM) (10% FBS, 1% penicillin/streptomycin). The following day the cells were transfected with 500 ng of plasmid DNA encoding the full-length WA1 SARS-CoV-2 spike protein behind a CMV promoter using polyethylenimine. After 5 h the media was changed, and cells were grown for an additional 20 h. S-BAT and S-BAT* were diluted to 10 nM in complete media and incubated with cells for 1 h. Media was removed, and cells were washed 3× with complete media. Live cell NanoGlo (Promega) was diluted in complete media, and 1 mL was added to the cells. Cells were imaged on a ChemiDoc XR (BioRad) imaging system with a 10 s exposure time.

**SARS-CoV-2 Virus Culture and Detection.** All SARS-CoV-2 live virus experiments were performed in a biosafety level 3 facility with approved procedures at the Gladstone Institutes. SARS-CoV-2 isolates and variants USA-WA1/2020, B.1.351 (Beta), and B.1.617.2 (Delta) were procured from BEI Resources. The virus was cultured in Vero-E6 cells (obtained from ATCC and grown in DMEM (Corning) supplemented with 10% FBS (GeminiBio), 1% glutamine (Corning), and 1% penicillin/streptomycin (Corning) at 37 °C, 5% CO2). Stocks were stored at −80 °C. Virus titer was determined via plaque assays on Vero-E6 cells. Briefly, 0.2 × 106 cells per well were seeded in 12-well plates, incubated overnight, and infected with a range of virus dilutions (10−6–10−5) for 1 h prior to overlay by 2.5% Avicel (Dupont, RC-591). After 72 h, the Avicel was removed, and cells were fixed in 10% formalin for 1 h and stained with crystal violet for 10 min to visualize plaque-forming units.
