Climate Variability, Snowmelt Distribution, and Effects on Streamflow in a Cascades Watershed

EXTENDED ABSTRACT

Cascades Range rivers provide critical water supply for agriculture, ecosystems, and municipalities in the Pacific Northwest, and they derive much of their water from snowmelt filtered through groundwater aquifers. Recent analyses show that this region is particularly sensitive to current and projected climate warming trends, specifically reduced snow accumulation and earlier spring melt (Mote, 2003; Stewart et al., 2005). By 2050, Cascades snowpacks are projected to be less than half of what they are today (Leung et al., 2004), potentially leading to major water shortages. Broad regional-scale characterizations identify climatic gradients as the most important controls on spatial variability in streamflow regimes, but the potential for other hydrological factors, particularly groundwater, to influence this response has received much less attention. Our objective is to develop an understanding of how discharge from a groundwater-dominated watershed is controlled at the event, seasonal, and interannual scales by snowpack dynamics, antecedent conditions, and global climate signals.

The study watershed is that of the McKenzie River at Clear Lake (Figure 1), in the central Oregon Cascades, includes extensive areas of high permeability Quaternary (High Cascade) basalts that result in a substantial groundwater system, as well as runoff-dominated Tertiary (Western Cascades) landscapes (Sherrod and Smith, 2000; Tague and Grant, 2004). This 239 km² watershed has long-term records of streamflow from United States Geological Survey gage #14158500. It also has record of precipitation, snow, and temperature from three Natural Resources Conservation Service SNOTEL sites: Hogg Pass (1451 m, 21E05S), Santiam Junction (1143 m, 21E06S) and Jump Off Joe (1067 m, 22E07S). Annual precipitation in the watershed ranges from ~1.8 to 3 m, and 70% falls between November and March. 47% of the watershed lies between 918 and 1200 m, in the transient snow zone. From 1200 m to the peak elevation (2051 m), seasonal snowpacks occur from November through June. Peak snow water equivalent (SWE) occurs around April 1st at Hogg Pass, and around March 1st at Santiam Junction and Jump Off Joe.

In order to examine relationships between hydrological variables in space and time, we performed Pearson’s correlations, autocorrelations, and cross-correlations using 42 parameters derived from discharge, precipitation, SWE, and temperature from the stations listed above. We also correlated discharge and SWE with monthly values of the Niño 3.4 index of sea surface

A simple water balance was constructed for the 2001–2004 water years, using values for the average basin elevation (1215 m) interpolated from precipitation and SWE values at Jump Off Joe and Hogg Pass. Basin-averaged evapotranspiration was calculated in RHESSys (Tague and Band, 2004). Predictive models of September–November minimum discharge were developed using stepwise regression in SAS 9.1.

Fluctuations in discharge are muted relative to daily variability in the recharge (rain plus snowmelt) signal (Figure 2). Summer streamflows are sustained by groundwater, not snowmelt. There is a high degree of discharge auto-correlation for ~2.5 months, and there is a strong cross-correlation between the previous year’s precipitation and the current year’s discharge at a 1 year lag. The El Niño-Southern Oscillation is a reasonably good predictor of SWE and a moderate predictor of annual discharge. Interannual variability in the 26-year SNOTEL record masks any long-term trends in precipitation or SWE, but the longer discharge records suggests that climate warming is altering the streamflow regime at Clear Lake. The hydrograph temporal center of mass (Stewart et al., 2005) has moved earlier by a statistically significant 15 days since 1950, which is probably a function of relatively more winter rain and earlier snowmelt. This finding is in line with other watersheds throughout the mountainous west (Stewart et al., 2005). September–November minimum flows have declined since 1947, probably as a result of longer summer recession periods resulting from earlier snowmelt.
The main conclusions of this study are:

1. In the study watershed, pronounced seasonal variability of water inputs is damped by extensive groundwater systems. The study area may serve as a model for other groundwater-dominated watersheds in the mountainous west.

2. Delays between precipitation and discharge are a function of snowpack storage and slow release of groundwater. From July to October, streamflow is sustained by groundwater.

3. Groundwater-dominated watersheds are somewhat buffered from <2-year fluctuations in precipitation, but are susceptible to prolonged droughts or wet periods.

4. Snowpack is more sensitive than discharge to the state of major of climate indices in groundwater-dominated watersheds.

5. Minimum flows are largely controlled by the current year’s precipitation, but are also sensitive to the timing of snowmelt and the antecedent conditions in the aquifer.

6. Regional warming of the past several decades has affected the shape of the annual hydrograph, in terms of its temporal center and minimum flows. Continued warming is predicted to lead to loss of snowpack and continued decline in minimum flows.
