The twist degree of freedom provides a powerful new tool for engineering the electrical and optical properties of van der Waals heterostructures. Here, we show that the twist angle can be used to control the spin-valley properties of transition metal dichalcogenide bilayers by changing the momentum alignment of the valleys in the two layers. Specifically, we observe that the interlayer excitons in twisted WSe$_2$/WSe$_2$ bilayers exhibit a high (>60%) degree of circular polarization (DOCP) and long valley lifetimes (>40 ns) at zero electric and magnetic fields. The valley lifetime can be tuned by more than 3 orders of magnitude via electrostatic doping, enabling switching of the DOCP from ~80% in the n-doped regime to <5% in the p-doped regime. These results open up new avenues for tunable chiral light-matter interactions, enabling novel device schemes that exploit the valley degree of freedom.

DOI: 10.1103/PhysRevLett.124.217403

Valleys represent the crystal momentum states where bands have an extremum [1–6]. Charge carriers or excitons in different valleys can exhibit markedly distinct properties [1], including different spin, optical selection rules, and Berry curvature, leading to a wealth of new physical phenomena such as the valley Hall [7,8] and Nernst effects [9,10]. Moreover, the valley degree of freedom can enable new ways of encoding and processing information beyond traditional schemes based purely on charge [11–13]. The realization of such applications relies on efficiently initializing a large valley polarization and achieving long valley and exciton lifetimes.

Transition metal dichalcogenides (TMDs) are a promising platform for valleytronics, as they host tightly bound excitons with coupled spin-valley properties that can be optically addressed via circularly polarized light [2,14–17]. A major obstacle to harnessing these properties in monolayer TMDs is the short lifetimes of intralayer excitons (0.1–1 ps) resulting from the sizeable electron-hole wave function overlap [18,19], as well as rapid valley mixing caused by exchange interactions [20–24]. Interlayer excitons in bilayer TMDs [13,25,26], consisting of an electron and a hole residing in two distinct TMD layers, present a promising route for overcoming these limitations. Because of the reduced wave function overlap, interlayer excitons can exhibit enhanced lifetimes that are 3–4 orders of magnitude longer than their intralayer counterparts [25,26] and tunable by an electric field [27].

Unfortunately, interlayer excitons in naturally occurring TMD bilayers exhibit rapid valley mixing, because valleys of opposite chirality are degenerate in energy and momentum [Fig. 1(a), top] [1,27–29]. Moreover, natural bilayers are inversion symmetric (the two layers are rotated 180° relative to each other); thus, as a whole, they do not exhibit net valley polarization [28,30] unless the symmetry is broken, e.g., with an electric field [31]. Consequently, most valleytronic studies involving interlayer excitons have focused on heterobilayers made of two different materials, such as WSe$_2$/MoS$_2$ [32] and MoSe$_2$/WSe$_2$ [12,13,33,34].

In this Letter, we show that the introduction of a twist angle between the layers can provide a new avenue for engineering the spin-valley properties of TMD bilayers, including homobilayers. Previously, the twist angle has been used to modify the resonance energy of excitons [35,36] and alter their properties due to moiré-induced spatial confinement and hybridization of bands [37–42]. Here, we tune the twist angle between the layers to control the momentum alignment of their respective valleys [Fig. 1(a), bottom], permitting long-lived interlayer exciton states with slow valley depolarization even at zero electric and magnetic fields. Importantly, we also demonstrate that the exciton and valley dynamics of twisted bilayers can be tuned via electrostatic doping.

To experimentally demonstrate twist-based spin-valley engineering, we fabricate optically addressable field-effect transistors that incorporate twisted WSe$_2$/WSe$_2$ bilayers ($t$-WSe$_2$/WSe$_2$) encapsulated in hexagonal boron nitride...
The devices feature top and bottom graphene gates for independent control of doping and vertical electric field [27]. Using the tear-and-stack technique [44,45], we fabricate multiple such devices from high-quality exfoliated flakes, with target twist angles ranging from 0° to 17°. For comparison, we also make a device using a 2H-stacked natural bilayer (labeled as 180°).

Figure 1(c) shows polarization-resolved photoluminescence (PL) spectra from bilayers with varying twist angles. All spectra are collected in the intrinsic regime. Solid (dashed) lines represent co- (cross-) polarized emission. \(X_0\) and \(X_I\) indicate intralayer and interlayer exciton emission, respectively.

As the twist angle is increased from 0° to 17°, the interlayer exciton peaks blueshift by almost 80 meV, and the lower-energy peaks between 1.5 and 1.6 eV (\(X_I\)) are attributed to interlayer transitions [16,27,53,54]. This assignment is based on our measurements of the out-of-plane electric field dependence [Fig. 2(a), Supplemental Sec. II, and Supplemental Fig. S2 [43]], which show a zero (non-zero) linear Stark shift for intralayer (interlayer) excitons, consistent with previous studies [26,27]. Despite their weaker binding energies [26], the interlayer excitons have lower energies than the \(K-K\) intralayer excitons, indicating that they do not originate from the momentum direct \(K-K\) transition. Instead, the interlayer excitons arise from lower-energy transitions that are momentum indirect, as previously predicted for multilayer TMDs [16]. In particular, the interlayer exciton PL in natural bilayer WSe\(_2\) was previously attributed to the \(K-Q\) transition [27].

FIG. 1. Band engineering through twisting. (a) Side view and Brillouin zone alignment of natural (2H-stacked, top) and twisted homobilayers (bottom). The \(K\) and \(K'\) points are aligned in natural bilayers, but not in twisted structures. (b) Device schematic (top), illustration of a moiré pattern in a twisted WSe\(_2\)/WSe\(_2\) bilayer (bottom left), and optical image of a device (bottom right). (c) Polarization-resolved PL spectra from bilayers with varying twist angles. All spectra are collected in the intrinsic regime. Solid (dashed) lines represent co- (cross-) polarized emission. \(X_0\) and \(X_I\) indicate intralayer and interlayer exciton emission, respectively. (d) Degree of circular polarization calculated from the PL spectra in (c). While the natural bilayer (red) exhibits almost zero interlayer DOCP, the twisted devices show DOCP as high as 60%.

We note that similar multipeak structures in twisted five interlayer exciton peaks separated by 15

observed even in natural bilayers (as in Ref.[27]), and their the confinement of interlayer excitons in moiré supercells[38]. In

between co- and cross-polarized emission signals between the two layers, as evidenced by the contrast in experimental and theoretical studies are necessary to confirm this asymmetry[28].

Next, we investigate the gate dependence of the interlayer excitons and their valley properties in the 17°-twisted bilayer device. Figures 2(a) and 2(b) show the electric field dependence of PL and the corresponding DOCP, obtained by applying equal and opposite voltages to the top and bottom graphene gates to eliminate effects of doping. From the Stark shift of the interlayer excitons, we extract an electron-hole separation of 0.37 nm, signiﬁcantly smaller than the interlayer spacing, thus indicating that at least one of the carrier wave functions is partially delocalized between the layers. Importantly, both the extracted e-h separation and the DOCP are robust to the electric field, suggesting that the same interlayer exciton state dominates the PL signal at all fields explored here.

By instead applying equal voltages to the gates, we investigate the dependence on electrostatic doping in the absence of vertical electric field [Figs. 2(c)–2(d); see Supplemental Fig. S4 for similar behavior at a twist angle of 2°[43]]. In stark contrast to the electric field dependence, the DOCP is strongly dependent on doping. While the interlayer exciton DOCP exceeds 80% in the n-doped regime, it can be switched to almost zero (5%) in the p-doped regime [Fig. 2(d)]. The DOCP stays relatively constant within each of the doping regimes and switches abruptly at their boundaries [Fig. 2(d)]. As in previous studies, the intralayer excitons do not exhibit this strong asymmetry [28].

Time-resolved PL measurements of the 17° twisted bilayer sample provide further insight into the exciton and valley dynamics [Figs. 3(a)–3(c), corresponding DOCP in Fig. 3(d)]. In the intrinsic regime, we ﬁt the data with a biexponential decay [59] convoluted with the instrument response [dotted lines in Figs. 3(a) and 3(d)] and extract fast and slow timescales of τ1 = 0.1 ns and τ2 = 0.9 (1.0) ns for co- (cross-) polarized emission. Long interlayer exciton lifetimes are also observed for twist angles of 0° and 5°, which exhibit τ2 = 2.0 ns and τ2 = 3.3 ns, respectively (Supplemental Fig. S5 [43]). Similar to previous studies [24,60], we observe a 15 ps delay between the co- and cross-polarized emission, which causes a dip in the DOCP until both polarization branches reach the slow decay regime [Fig. 3(d)]. Fitting the DOCP in this regime with a linear coupled model (see Supplemental Sec. IV[43]), we extract a very long valley lifetime of 44 ns [dashed line in the inset in Fig. 3(d), lines corresponding to 5 and 10 ns

FIG. 2. Gate tunability of DOCP. (a) Out-of-plane electric field dependence of intra- and interlayer exciton PL from the 17°-twisted bilayer. While the intralayer excitons (X₀) do not shift with the electric field, the interlayer excitons (Xᵢ) exhibit a Stark shift equivalent to an electron-hole separation of 0.37 nm. Opposite voltages are applied to the two gates (the hBN flakes have the same thickness) to apply an electric field while keeping the TMD intrinsic. (b) Electric field dependence of DOCP, showing that the DOCP is largely insensitive to the electric field. (c) Doping dependence of PL emission for intra- and interlayer excitons. The same voltages are applied to the two gates to dope the sample without applying an electric field. (d) Doping dependence of DOCP, showing switching from large (>80%) values in the n-doped regime to almost zero (<5%) in the p-doped regime.

consistent with reduced interlayer coupling[35,36,55–57] [Fig. 1(c)]. In all twisted structures, we observe four or five interlayer exciton peaks separated by 15–17 meV. We note that similar multipeak structures in twisted MoSe₂/WSe₂ heterostructures have been attributed to the confinement of interlayer excitons in moiré supercells [38]. In t-WSe₂/WSe₂ studied here, the multiple peaks are observed even in natural bilayers (as in Ref. [27]), and their spacing is independent of the twist angle, suggesting a different origin. Since their energy separation is similar to the optical phonon energy in WSe₂[27,58], one possibility is that the peaks are phonon replicas [27]. Further experimental and theoretical studies are necessary to conﬁrm this hypothesis, however.

The spin-valley properties of the interlayer excitons change drastically with the introduction of a twist angle between the two layers, as evidenced by the contrast between co- and cross-polarized emission signals (I_co and I_cross, respectively) in PL measurements. Upon illumination with circularly polarized light, the natural bilayer emits almost equal I_co and I_cross, whereas t-WSe₂/WSe₂ emits much stronger copolarized light [Fig. 1(c)]. Defining the degree of circular polarization (DOCP) as (I_co − I_cross)/(I_co + I_cross), we ﬁnd that, while the neutral interlayer exciton DOCP remains close to zero in natural bilayers, it reaches values as high as 60% in twisted bilayers [Fig. 1(d); see also Supplemental Fig. S3 and Supplemental Sec. III[43]]. Such high DOCP suggests much slower valley depolarization dynamics in t-WSe₂/WSe₂.
rapidly in the $n$- and $p$-doped regimes, respectively. Fitting the data with the linear coupled model [43,60] [dashed lines in Figs. 3(b)–3(d)], we find that the initial exciton decay rate is faster in the $n$-doped regime ($\tau_1 = 40$ ps) than in the intrinsic and $p$-doped regimes ($\tau_1 = 0.1$ ns). Conversely, the valley lifetime is longer in the $n$-doped regime ($\tau_v = 2.2$ ns) than in the $p$-doped regime ($\tau_v = 30$ ps, similar to the instrument response time).

The observed polarization properties and their doping dependence can be understood from the band structure of $t$-WSe$_2$/WSe$_2$ bilayers. In natural (2H) bilayer WSe$_2$, recent angle-resolved photoemission spectroscopy measurements [61,62] and density functional theory calculations [27,63] suggest that the conduction band minimum (CBM) and valence band maximum (VBM) are located at the $Q$ and $K$ points, respectively. Our results suggest that these band extrema are conserved in $t$-WSe$_2$/WSe$_2$, consistent with recent studies in 3R-stacked bilayer WS$_2$ [64]. The extracted electron-hole separation of $d = 0.37$ nm [Fig. 2(a)] is smaller than the interlayer separation of $d_0 \sim 0.6$ nm [26] but larger than $d_0/2$, as expected for a $K$ (hole) to $Q$ (electron) transition, where the hole is localized in a single layer and the electron is partially delocalized between the layers (see Supplemental Sec. II for further discussion [43]). In particular, the extracted dipole moment is in excellent agreement with recent DFT calculations for $0^\circ$ twisted bilayer WSe$_2$ [46], where the wave function at the $Q$ point was predicted to have a 62%–38% distribution between the two layers (see Supplemental Sec. V [43] for further discussion).

A key difference in the band structures of natural and twisted WSe$_2$ bilayers is that the $Q$ and $K$ points are spin degenerate in the former but not in the latter [65]. Therefore, electrons and holes in natural bilayer WSe$_2$ do not need to acquire any energy or momentum to change spin, enabling rapid depolarization [Fig. 4(a)]. In contrast, valley depolarization of neutral interlayer excitons in twisted structures requires both carriers to scatter with phonons, acquire energy, and flip their spins [24,59] [Fig. 4(b)]. This is a much slower process, and the dynamics are instead likely governed by electron-hole exchange interactions [12,59,66]. However, since the interlayer excitons are indirect in both real and momentum space, even exchange interactions are expected to be slow [12,13,67]. In particular, they should be substantially slower than for momentum direct intralayer excitons, where such processes cause very short valley lifetimes (1–10 ps) in the intrinsic regime [24,68,69].

The observed hierarchy of valley lifetimes in the three doping regimes, i.e., $\tau_v(\text{intrinsic}) > \tau_v(n\text{-doped}) > \tau_v(p\text{-doped})$, is also well described by our band-structure considerations. In the $p$- and $n$-doped regimes, the depolarization dynamics of charged interlayer excitons are dominated by intervalley scattering [12,59,66], and, in contrast to the intrinsic regime, only one of the carriers needs to scatter, due to the additional resident charge in the

...
The strong asymmetry in the degree of circular polarization shown in Fig. 2(d) is a result of the interplay between the depolarization and exciton decay dynamics, as implied from the expression $\text{DOCP}_{\text{tot}} = \text{DOCP}_0/(1+2\tau_1/\tau_v)$, where $\text{DOCP}_{\text{tot}}$ and $\text{DOCP}_0$ are the total (time-integrated) and initial DOCP, respectively. In the hole-doped regime, the depolarization timescale is shorter than $\tau_1$ (30 ps and 0.1 ns, respectively), resulting in a low DOCP ($<5\%$). In the electron-doped regime, on the other hand, $\tau_1$ is much longer than $\tau_1$ (2.2 ns and 40 ps, respectively), so the observed DOCP is very large ($>80\%$). Additionally, $\text{DOCP}_{\text{tot}}$ is also affected by variations in $\text{DOCP}_0$, which causes $\text{DOCP}_{\text{tot}}$ to be higher in the $n$-doped regime than in the intrinsic regime, despite the fact that $\tau_1/\tau_v \ll 1$ in both regimes.

In conclusion, we have shown that the twist angle provides a new route for engineering the chiral optical properties of interlayer excitons in WSe$_2$/WSe$_2$ bilayers. Specifically, by changing the momentum separation of the valleys in the two layers, we achieve large valley polarization for long-lived interlayer excitons in $t$-WSe$_2$/WSe$_2$, in contrast to natural bilayers. Such valley polarization, which can be initialized and read out optically, is a direct consequence of the valley lifetime greatly exceeding the exciton lifetime. Moreover, in agreement with band structure considerations, the valley dynamics are highly tunable by electrostatic doping, enabling switching of the DOCP from more than 80% in the $n$-doped regime to $<5\%$ in the $p$-doped regime. Our results exemplify the power of twist-based engineering in van der Waals heterostructures and demonstrate that twisted TMD bilayers are a new promising platform for tunable chiral photonics and electrically switchable spin-valley-based devices. The coupling to functional structures, such as plasmonic metasurfaces [70–72], can further enhance chiral light-matter interactions and enable routing of electrically switchable chiral photons, thus opening up avenues for applications in quantum information storage and processing.

FIG. 4. Depolarization mechanisms in natural and twisted WSe$_2$/WSe$_2$ bilayers. (a) Depolarization in natural bilayer WSe$_2$ occurs simply through two spin-flip transitions (curved arrows), causing low DOCP. Magenta (cyan) bands indicate spin up (down) for electrons. The thickness of the dashed lines qualitatively represents the relative dominance of the $\sigma_+$ and $\sigma_-$ recombination processes. Inset: Brillouin zone showing the location of the degenerate $K$ and $Q$ points of a natural bilayer as a whole. (b) Depolarization in twisted bilayer WSe$_2$ requires both a phonon-induced momentum kick (straight arrows) and a spin-flip transition (curved arrows) for both carriers, resulting in high DOCP and long $\tau_v$. (c),(d) Since positively (negatively) charged excitons already have holes (electrons) at both the $K$ and $K'$ ($Q$ and $Q'$) points, only the electron (hole) must flip spin and shift in $k$ space.

opposite valley. Positively charged excitons, which already have resident holes in both the $K$ and $K'$ valleys, require only scattering of the electron to depolarize [Fig. 4(c)]. Conversely, only the hole needs to scatter in negatively charged excitons [Fig. 4(d)]. These considerations indicate that the valley lifetime should be shorter in the doped regimes than in the intrinsic regime, as observed here. Our results in Fig. 3(d) suggest that the depolarization mechanism for holes is slower than for electrons in our twisted structures, consistent with the large spin-orbit coupling at the $K$ point VBM and the resultant strong spin-valley locking for holes [28]. This is also in good agreement with a recent study on 3R-stacked bilayer WS$_2$ [64].

With regards to exciton lifetimes, we note that their doping dependence is influenced by various recombination processes, including both radiative and nonradiative ones. Further experimental and theoretical studies will be necessary to obtain a full understanding of the underlying microscopic phenomena that determine the doping dependence of exciton lifetimes.
