Introduction to H₂S Scavenging

Hydrogen sulfide (H₂S) scavenging, or “gas sweetening,” is a crucial aspect in ensuring trouble free upstream and downstream operations. This GATEKEEPER presents different methods of H₂S scavenging, including scavenging mechanisms, application considerations, and advantages & disadvantages for each method.

Natural gas is considered sour if it contains significant amounts of H₂S, generally 4 parts per million (ppm) or greater. Sour gas is caused due to development of shale oil & gas plays, efforts to increase field life, and the use of Enhanced Oil Recovery (EOR) methods like water injection often result in reservoir souring. High H₂S concentrations in produced gas creates safety hazards for operations, increases corrosion and sulfide-stress-cracking risks, and results in an export gas of lower value. To minimize these factors, various H₂S removal methods can be utilized.

H₂S Remediation Methods

There are multiple treatment strategies to remove H₂S from produced gas. The optimal strategy depends on a variety of factors, including H₂S concentration, residence time, space & weight considerations, OPEX/CAPEX, and volume of gas to be treated. Operating conditions also influence the selection of treatment strategies and application locations. The most common methods have been presented in this GATEKEEPER.

Solid Scavengers

Solid scavengers are very effective in stripping H₂S from gas streams down to trace levels. They require significant CAPEX and are often labor intensive during media change out. However, they require little OPEX, are predictable in their removal rates, generally do not require additional chemicals, and generally do not impact downstream processes or overboard water.

Metal Oxides

These systems comprise of a fixed bed filled with absorbent material of metal oxides such as zinc, copper, iron, or magnesium. These beds take up significant space and require two trains to maintain operation during servicing. The media is non-regenerative and requires significant time and labor to charge with fresh media. Confined space entry and potentially pyrophoric waste create unwanted operations hazards. These systems are very efficient in removing almost all the H₂S from a gas stream, are highly reliable, and very predictable in their removal rates and change cycles. See Figure 1 for a typical metal oxide medal bed design.

Regenerative Solid Bed

Regenerative solid beds, also known as molecular sieves, remove H₂S by adsorption instead of chemical reaction. They are comprised of aluminosilicate crystalline polymers (zeolites), which strip out polar or polarizable compounds. While this includes H₂S, molecular sieves will also remove CO₂, water, methanol, mercaptanes and sulfides, ammonia, mercury, and aromatics to trace levels. H₂S is preferentially removed over CO₂ and allows for selective removal from streams containing both.

Highly effective at removing contaminants to trace levels, the zeolites can be regenerated using a regeneration gas stream; this gas stream must then be treated to remove the sulfur species. This can be problematic as it requires dealing with a H₂S-rich gas stream. Large vessel size, limited capacity, and the need for parallel trains for regeneration during service can increase CAPEX and space requirements. Additionally, dealing with sulfur waste creates potential issues for both operations handling and OPEX considerations. Figure 2 illustrates the molecular sieve removal and regeneration process. Figure 3 illustrates the range of sizes and shapes molecular sieve media can be formed into.
Liquid Scavengers

Liquid scavengers generally take up less space and weight than solid scavengers, but are significantly less efficient. OPEX is increased compared to solid scavengers, but liquid scavengers offer more options for retrofitting an existing facility. Liquid scavengers fall into two categories: regenerative and non-regenerative.

Regenerative: Amine Wash

Amine contactor towers are the most commonly used method of gas sweetening in the industry. Sour gas is passed through a contactor column filled with an amine solution, which reacts with H₂S to form acid/base salts in a fully reversible reaction. H₂S preferentially reacts, but CO₂ may also react with the amine. This "rich" amine solution is sent to the regenerator column, where it is heated and depressurized to release the acid gases and produce "lean" amine. The "lean" amine is then fed back into the contactor column. The waste gas stream must be disposed of. This process is primarily used where large quantities of H₂S must be removed, or high-volume gas streams are involved; removal rates are in tons per day of H₂S. Contactor tower and regeneration system footprint can be significant with high-volume or high H₂S streams.

Regenerative: Reduction-Oxidation

The reduction-oxidation (redox) systems' method is similar to the amine wash process. Redox systems usually use iron and chelating agents for the reaction. Sour gas passes through an absorber column where the H₂S is stripped from the gas. This spent solution is sent to an oxidizer unit to regenerate. The iron is initially reduced from ferric (Fe³⁺) to ferrous (Fe²⁺) by the H₂S, then oxidized back to the ferric in the oxidizer unit. The oxidation process produces a H₂S-rich waste gas stream, but can also result in elemental sulfur production due to the reactivity of the oxidizing agents. This process can be used to remove several tons of H₂S per day, or where complete stripping of sulfur is required.

Non-regenerative: Aldehydes

Aldehydes bind to the H₂S in a reaction across the aldehyde double bond. The most commonly used aldehyde is formaldehyde; alternatives include glyoxal, acrolein, and glutaraldehyde. In general, aldehydes are not used due to their high toxicity, potential to create explosive environments, carcinogenic nature, and handling issues. Glyoxal has lower environmental impact than other aldehydes, but is known to cause hydrate formation. HMTA (hexamethylenetetramine) is a safer alternative used in acid stimulation, but it produces an oily film that makes it problematic for many applications. Some aldehydes can reversibly react at higher temperatures, releasing H₂S back into the system.

Non-regenerative: Triazine

Triazine is the most commonly used non-regenerative liquid H₂S scavenger used in the industry. Reaction byproducts are biodegradable and can be disposed of in overboard waters. Unreacted triazine is highly toxic to aquatic life and overtreatment should be minimized to the extent possible. Reaction products are soluble in oil or water phase, depending on the vendor-specific formulation. In high calcium waters, triazine can cause carbonate scaling due to increase of the system pH. Direct injection application has limited efficiency as to H₂S dissolving into the product is the rate-limiting step; contactor/bubbler towers or wetted media can easily double H₂S removal efficiencies, but increase the footprint of the system.

Non-regenerative: Other Options

Buffered nitrate/nitrite solutions have similar removal capacity compared to triazine. While cheaper than triazine, calcium nitrate produces nitrogen oxides, nitric acid, and insoluble precipitates from reacting with H₂S. Caustics can be used to strip H₂S from gas. The removal capacity of caustics is significantly lower than other options and caustic poses safety risks. Bisulfides can be used, but produce colloidal sulfur resulting in severe corrosion problems. Strong oxidizers, like caustics, poses safety risks for use and handling. The reaction rate is very rapid, making oxidizers a good solution for very low levels of H₂S. Combinations of amines and aldehydes can be used to create in-situ formaldehyde for H₂S scavenging. This reduces the environmental issues of formaldehyde, but maintains the usage issues of both aldehydes and amines. Performance is limited by the rate at which the aldehyde and amine react to form the free formaldehyde.

Biological Scavengers

Biological processes selectively remove H₂S by utilizing it in bacterial respiration, converting it to mercaptanes or elemental sulfur and sulfate. The operating temperature range is very limited due to the biological nature of the process. Exotic metallurgy is required for the equipment in this process. It is effective at removing up to 40 tons per day of H₂S, but is only viable when sulfur recovery byproducts are economically disposed of or sold off.

Conclusion

While a variety of H₂S removal methods exist, selecting the best method for a facility involves demand, space, and CAPEX/OPEX considerations. The most commonly used method for the oil & gas industry tend to be liquid scavengers in the form of amine towers or triazine direct injection. If footprint space allows, triazine contactor towers can greatly increase efficiency and reduce OPEX.
