CLINICAL QUESTION
What is the best available evidence on effectiveness of exercise for healing venous leg ulcers (VLUs)?

SUMMARY
Venous leg ulcers (VLUs) are chronic wounds that occur on the lower leg due to venous disease. (Level 1).

Evidence from small clinical trials suggests that range of motion, strength and aerobic exercises (including walking) are effective in improving strength1 and flexibility2, 3. Although there is no strong evidence that this translates to improvements in VLU healing2, 4-6 people with VLUs did experience improvements in objective measures of calf muscle pump function (e.g. ejection fraction) when they participated in exercise programs1, 4, 5 (Levels 1 and 2).

BEST PRACTICE RECOMMENDATIONS
All recommendations should be applied with consideration to the wound, the person, the health professional and the clinical context.

Advise individuals with VLUs to engage in exercises designed to improve calf muscle pump function, in addition to compression therapy (Level B).

Recommend walking, calf muscle resistance exercise, ankle stretches and ankle circling, preferably in a supervised program, for promoting improvements in venous function. (Grade B).

SOURCES OF EVIDENCE
This evidence summary is based on a structured database search using variations of the search terms describing VLUs and exercise. Searches were conducted in EMBASE, Medline, AMED and the Cochrane Library for evidence from 1990 to November 2019 in English. Where high level evidence was available, lower level evidence was not reviewed. Levels of evidence for intervention studies are reported in Table 1.

BACKGROUND
Venous leg ulcers occur due to venous insufficiency. Venous insufficiency describes a condition in which the venous system does not carry blood back to the heart in the most efficient manner, causing blood to pool in the veins of the lower limbs.

Venous insufficiency occurs due to:7, 8

- previous blood clots,
- impaired valves in the veins in the lower leg do not close sufficiently after each muscle contraction, allowing blood to flow back to a previous section of the vein (venous reflux), and
- calf muscle pump function not adequately assisting in returning blood to the heart.

Contraction and relaxation of the two calf muscles surrounding the deep veins in the leg assist in venous return. Blood pools in the veins of the legs when the calf muscles are relaxed, and contraction of the muscles compresses the veins, pushing blood back to the heart.6, 9-11 Function of the calf muscle pump requires adequate ankle motion and muscle strength to promote venous return, which is best achieved during heel-to-toe walking.9, 11, 12 Evidence from small studies indicates that individuals with venous disease and VLUs have inadequate calf pump muscle function, which contributes to their disease severity.13 Exercise to improve muscle strength and ankle flexibility might improve venous return.14

CLINICAL EVIDENCE

In most studies reported below, exercise was an adjuvant to compression therapy (Levels 1 and 2).1-6

Exercise for improving lower limb strength and flexibility

Results from clinical trials1-3 conducted in people with VLUs support the rationale that undertaking exercise can improve strength and flexibility.

A study (n = 39)2 showed that a 12-week supervised exercise program improved performance in aerobic exercises at both 3 months and 12 months. Improvements in ankle flexibility and range of movement that were achieved at 3 months were not sustained by 12 months2 (Level 1).

A second RCT (n = 32)3 explored the impact of a program consisting of standing heel raises, ankle circling exercises, walking and stationary cycling. After 9 weeks, the exercise group had significant improvements in range of ankle dorsiflexion (mean increase 3.8º, p < 0.001), plantar flexion (mean increase 4º, p < 0.001) complete ankle range of motion (mean increase 8.3º, p < 0.001). These results were significant (p < 0.05) compared with a control group that had lesser improvement in ankle flexibility3 (Level 1).

In a non-randomized trial (n = 21),1 people with VLUs undertook isotonic calf muscle strengthening exercises (plantar flexions performed under weight resistance). After seven days, the exercise group had a significant 135% increase in measures of calf muscle endurance (p < 0.001)1 (Level 2).

Exercise for improving venous signs and symptoms

Most of the available evidence on the effectiveness of exercise in improving venous signs and symptoms is conducted with individuals with venous disease that has not progressed to ulceration. However, there is some evidence that the findings extend to individuals with VLUs.1, 4, 5

One RCT (n = 21)4 evaluated progressive resistance exercises compared to no exercise program. The intervention regimen included individualised heel raise exercises that were progressively adjusted over 12 weeks. There were no significant differences between the exercise group and the no-exercise group for most measures of venous function including, venous volume, venous filling index, ejection volume, residual volume or residual volume fraction. The only measure of venous functioning that showed differences associated with heel raise exercise was ejection fraction, which improved for individuals who engaged in exercises (mean difference in change 18.5%, 95% confidence interval [CI] 0.03 to 36.6%, p < 0.05)4 (Level 1).

A second RCT (n = 13)5 compared a daily exercise program of seated, standing and one-leg heel raises compared to normal care. At 12 weeks, the intervention group showed significant improvements in ejection fraction compared to baseline (p = 0.03) and compared to the control group (p = 0.05)5 (Level 1).

In the trial by Kan and Delis (2001)1 (see above), the exercise group had a significant 67.5% improvement ejection venous volume compared to baseline (median improvement 28.5mL, 95% CI 20.5 to 35.5mL). Significant improvements were also achieved in ejection fraction (p = 0.06), residual venous volume (p = 0.06), and residual volume fraction (p = 0.08). There was no significant change in venous filling index (p = 0.54) or venous volume (p>0.5)1 (Level 2).
Exercise for healing VLUs

Although the evidence above\(^1,4,5\) suggests that strength and flexibility exercises are associated with improvements in measures of venous function, this may not translate to improved healing of VLUs. Evidence from small studies,\(^2,4-6\) generally with good adherence rates\(^2,5\) and follow-up of between 12 weeks\(^4-6\) and 12 months\(^2\) has not demonstrated improvements in VLU healing.

The largest RCT (n = 35) investigated the effect of a 10,000 steps per day walking program on VLU healing. The percent of VLUs completely healed at 12 weeks was not significantly different to VLUs that healed in a non-exercise group (83% versus 76%, p = 0.128).\(^6\) However, there was a significant relationship between the number of daily steps taken and VLU healing time (p = 0.08). Lack of significant improvements in overall healing rates may have been influenced by the low rate of success (33% of participants) in reaching the daily goal of 10,000 steps\(^6\) (\textit{Level 1}).

The RCT by Jull et. al. (2009)\(^4\) (see above) that evaluated progressive resistance exercises compared to no exercise, also reported VLU healing outcomes. There were no significant differences in changes in VLU size for individuals who participated in the exercise program compared to the control (p = 0.13). There was also no difference between the groups for time to complete healing (odds ratio [OR] 0.55, 95% CI 0.16 to 1.95)\(^4\) (\textit{Level 1}).

Similarly, the RCT by O’Brien et. al. (2013)\(^5\) (see above) that reported on a heel raise program found no significant impact on complete healing (p = 0.74), reduction in wound surface area (p=0.34) or ulcer condition measured using the Pressure Ulcer Scale for Healing (PUSH) (p = 0.35) (\textit{Level 1}).

Another RCT (n = 39)\(^2\) evaluated the feasibility of a 12-week (36 sessions) supervised exercise program consisting of aerobic, resistance and flexibility exercises for individuals with VLUs. In this study, the exercise group experienced a higher VLU healing rate (83% versus 60% at 12 months) and a shorter median time to healing (13 (3.9 to 52) vs. 34.7 (4.3 to 52) weeks). However, statistical significance of healing outcomes was not evaluated\(^2\) (\textit{Level 1}).

ABOUT WHAM EVIDENCE SUMMARIES
WHAM evidence summaries are consistent with methodology published in

Methods are provided in detail in resources published by the Joanna Briggs Institute as cited in this evidence summary. WHAM evidence summaries undergo peer-review by an international review panel. More information on the website: http://WHAMwounds.com.

WHAM evidence summaries provide a summary of the best available evidence on specific topics and make suggestions that can be used to inform clinical practice. Evidence contained within this summary should be evaluated by appropriately trained professionals with expertise in wound prevention and management, and the evidence should be considered in the context of the individual, the professional, the clinical setting and other relevant clinical information.

PUBLICATION
This evidence summary has been published in Wound Practice and Research:
